INDEX TO VOLUME II.

[The Names of the Authors whose writings are abstracted or reviewed in the 'London Medical Record' are given at the head of the List under each Letter.]

A **BRAHAM**, Mr., 215; Adamiewicz, M. A., 805; Adams, Dr. A. L., 537; Allbutt, Dr., 88, 600; Allen, Mr. A. H., 53; Alyschewsky, Dr., 712; Amussat, Dr., 56, 412; Andrews, Dr. E., 505; Andrews, Dr. J. B., 297; Arling, M., 370, 662, 743; Arlt, Dr., 209, 223, 240, 258, 272, 288, 462; Arnstein, Dr., 261; Ashfield, Dr., 341; Ashhurst, Dr., 632; Asp, Dr. G., 789; Atthill, Dr., 72; Auspitz, Dr., 829; Awater, Dr., 571; Azéma, M., 404
Abdomen: prolapse of omentum through wound of (Horak), 470; fibroma of (Gersuny), 697; drainage of (Hahn), 762
Abdominal section: a remedy for intussusception (Ashhurst), 632
Abdominal supporters (Goodell), 445
Abdullah Bey, 592
Abiogenesis (Huizinga), 563
Abortion: incipient, use of chloral hydrate to prevent (Besnier), 41; opium and chloral in (Besnier), 167
Absorption: by large intestine (Czerny and Latschenberger), 145, 160
Academy: of Sciences in Paris, nominations to, 172; of Medicine, prizes of, 220
Accommodation: of eye, mechanism of (Fumagalli), 325
Accephalia: case of (Huber), 378
Acetonæmia: death from, in a diabetic patient (Berti), 567
Aconite: Nepal (Groves), 52
Aconitines (Groves), 52
Adulteration: of food (Hardwicke), 120; (Whitmore), 183; (Cameron), 279; prosecutions for, 154; of milk (Vöelcker), 168; of scammony, 800
Adults: temporary paralysis in (Frey), 83
Aerated waters: contamination of, 540
Agassiz: brain of (Wyman), 173
Agricultural products: influence of chemical vapours on (Cameron and Angus Smith), 172
Air: microscopic characters of dust in, 17; in blood-vessels (Kowalewsky and Wyssotsky), 261; compressed, operation of (Liebig), 472; underground, 556, sea and mountain, comparative effects of, 815
Albumen: and casein (Béchamp), 437
Albuminoid matter: combination of chloral with (Personne), 100
Albuminoid substances: influence on electro-capillary phenomena (Onimus), 211
Alcohol: effects of (Parkes), 144; physiological action of (Dogiel), 253; influence of, on temperature (Riegel), 293; influence of, on heart (Adams), 537; effects on nervous system (Hammond), 721
Alcoholism: nux vomica in (Luton), 167; distinction from dipsomania, 784
Alder: black, bark of (Ince), 391
Algeria: mineral waters in, 314
Allen, Dr. P., death of, 60
Allen's bidet and enema-douche, 281
Alopecia: congenital (Schedi), 91; fungus of (Courrèges), 408; (Malassez), 636
Amazon tribes: 16
Amblyopia: alcoholic, bromide of potassium in (Quaglino), 324
Amenorrhæa: galvanism in (Whitaker), 735
America: North, mineral springs of (Moorman), *rev.* 106; men and animals in, 313
Ammonia: in cholera (Declat), 440; treatment of snake-bites with (Kleinschmidt), 487
Ammoniaemia (Felz and Ritter), 246
Amputation: of penis (Jullien), 118; without

hæmorrhage, 154; of metatarsal bones (Despres), 214; at shoulder-joint (Miner), 214; of tongue in a child (Caselli), 323; simple ligature a means of preventing hæmorrhage in (Colletti), 452; of humerus by elastic ligature (Grandesso-Silvestri), 698
Amyl: nitrite of, in asthma and bronchitis (Kitchen), 264; action of (Veyrières), 343
Anæmia: influence of, on nutrition of heart (Perl), 295; transfusion of blood in (Béhier), 569; use of mineral waters in (Gubler), 660
Anæsthesia: local, from saponin (Koch), 67; use of ether for, 155; by injection of chloral into veins (Ore), 181, 375; (Warlomont and others), 753; production of, by compression (Le Fort and others), 471
Anæsthetics: use of, in Schiff's laboratory (Hake), 468; influence of, on vaso-motor centres (Bowditch and Minot), 514
Anatomy: text-books of, 589
Aneurism: traumatic, mechanics of (Roser), 14; popliteal, treated by introducing horse-hair (Bryant), 87; femoral, treated by injection of ergotin (Plagge), 87; abdominal (Kulischer), 177; false, of anterior tibial artery (Leisrink), 230; transcranial arterio-venous (Rizzoli), 256; traumatic, of dorsalis pedis artery (Azéma), 404; of branches of pulmonary artery, 460; ilio-femoral, ligature of common iliac artery for (Barbosa), 625, 643; of left subclavian artery, distal ligature in, 760
Aniline: use of, for colouring sausages, 428
Animals: domestic, leucocythæmia in (Bollinger), 320, 337; as motor powers, 672
Ankylosis: fibrous (Sayre), 737
Anstie, Dr., death of, 592
Antagonism: of poisonous substances (Martin-Damourette and others), 242
Anteversion: of uterus (Goodell), 430
Anthraxis: caused by copper-workers (Proust), 781
Antiseptic: fuchsin as an, 16; salicylic acid as an (Kolbe), 599; dressing, new (Lister), 716
Anus: tuberculous ulceration of (Martineau), 602
Aorta: pulsation of subclavian artery as a sign of dilatation of (Fauvre), 356; pulsation of retinal arteries in disease of (Grandclement), 538
Aphasia: in general paralysis (Hanot), 421; pathology of (Richet), 485; in children (Clarus), 503
Apollinaris water, 91
Apomorphia: physiological action of (David), 647
Apothecaries: female, 592
Apothecaries Society: new act for, 492; regulations of, 576
Appetite: a large, 607
Areola: mammary, disease of preceding cancer of breast (Paget), 785
Army: British, spirit-ration in (Maclean), 223
Arnica: adulteration of (Holmes), 309
Arsenic: detection of in hydrochloric acid (Siebold), 101; physiological action of (Boehm), 419; chronic poisoning by (Malmsten), 441; poisoning by, in wall-papers, 448
Arteries: blood-pressure in (Müller), 388; superior thyroid and lingual, anomalies of (Bajardi), 730
Artery: internal carotid, hæmorrhage from, treated by ligature (Sands), 125; anterior

tibial, false aneurism of (Leisrink), 230; deep femoral, ligature of (Caselli), 246; femoral, ligature of, in elephantiasis (Leisrink), 281; lingual, ligature of, before extirpation of tongue (Weichselbaum), 352; subclavian, pulsation in, as a sign of dilatation of aorta (Fauvre), 356; dorsal of foot, aneurism of (Azéma), 404; pulmonary, aneurisms of branches of, 469; common iliac, ligature of, for ilio-femoral aneurism (Barbosa), 625, 643; gluteal, rupture of (Guillaumet), 634; pulmonary, influence of brain on blood-pressure in (Badaud), 756; left subclavian, aneurism of, treated by distal ligature (McLean), 760
Artesian wells: absence of oxygen in water, 444
Ash-constituents of food (Forster), 31
Ashantee Expedition: sanitarium in, 44; medical officers of, 154; sketch of (Colin), 270
Asphyxia: in infants, treatment by induced current (Lauth), 167; from insufficient oxygen (Le Blanc), 322
Aspiration: in retention of urine (Bell), 248; retropharyngeal abscess treated by (Lincoln), 621; in strangulated hernia (Roger), 634
Assafoetida: aromatic tincture of (Conner), 264
Association: of Medical Officers of Health, 136; of German Naturalists and Physicians, meeting of, 476, 638; Saint Andrew's Medical Graduates, final meeting, 540; British, for Advancement of Science, proceedings of, 557; German Public Health, proceedings of, 682
Asthma: nitrite of amyl in (Kitchen), 264; use of mineral waters in (Gubler), 675; inhalations in, 701
Astragalus: fracture of with double dislocation of foot (Romei), 134
Asylum: Royal Naval Lunatic at Yarmouth (MacLeod), 500
Ataxic patients: writing of, 235; spontaneous fractures and dislocations in (Bergeron), 402
Ataxy: locomotor, diagnosis of (Beard), 257
Atmosphere: microscopic characters of dust in, 17
Atrophy: progressive muscular, hereditary transmission of (Eichhorst), 13; morbid anatomy of (Lockhart Clarke), 386
Atropia: hypodermic injection of in tetanus (Miller), 248; pretended antagonism of hydrocyanic acid to (Boehm and Knie), 420
Auditory hallucinations (Nicolson), 410
Auditory vertigo (Charcot and others), 238, 254; (Burnett), 407
Australian meat: 140
Austria: the medical profession in, 363

B **BADAUD**, Dr., 756; Baillou, M., 217; Bailly, M., 670; Bajardi, Dr., 730; Balfour, Dr. G. W., 566, 681; Bandl, Dr. L., 669; Barbosa, Dr., 565, 625, 643, 717; Bardinet, Dr. 88; Bartels, Dr., 423; Barth, M., 416, 432; Bartholow, Dr., 285, 700; Baschieri, Dr., 698; Battey, Dr., 180, 695; Baume, M., 82; Beard, Dr. G. M., 202, 275, 324, 349, 474; Beardsley, Dr. C. E., 748; Béchamp, M., 437, 795; Béhier, M., 249, 569, 817; Beljaew, M., 260; Bell, M. J., 249; Bellini, Dr., 157; Benedikt, Dr., 112, 128, 514, 564, 619; Beneké, Dr. 815; Berger, Dr. O., 512; Bergeret, Dr., 72; Bergeron, M., 402, 406, 488; Bergonzoli, Dr., 452; Bernhardt, Dr., 61, 294, 650; Bernutz, Dr., 652; Berti, Dr., 536, 567; Besnier, Dr., 41,

- 91, 167; Betz, Dr., 177; Bezold, Dr. 379; Bidder, Dr. A., 389, 782, 811; Bigelow, Dr. J., 547; Bille, Dr., 605; Billroth, Dr., 87; Bing, Dr. A., 379; Binz, Dr., 301; Bizzozero, Dr., 714; Blachez, M., 550; Blackey, Dr., 530; Black, Dr. J. K., 506; Blanc, Dr. H., 440; Bligh, Dr. J. W., 358; Boardman, Dr., 344, 360, 367, 393; Bock, Dr., 295; Böhm, Dr., 419, 420, 757; Boguljubow, Dr., 260; Boileau, M., 357; Boinet, M., 568; Bollinger, Dr. O., 320, 337; Bond, Dr. F. T., 424; Bond, Mr. M., 216; Bond, Mr. T., 249; Bonafant, M., 441; Borrelli, Dr., 758; Böttger, Dr., 87; Bottini, Dr., 230; Bouchut, M., 230; Boudon, M., 503; Bouley, M., 249; Bourneville, M., 628; Bourguet, M., 213; Boutelle, Dr. J. T., 826; Bowditch, Dr., 514; Bazzolo, Dr., 714; Bradley, Dr. S. M., 7; Brandt, Dr. J., 265; Braun-Fernwald, Dr., 770; Braus, Dr., 298; Broca, M., 179; Brochin, M., 323, 341; Brouardel, M., 166; Brown, Dr. Crum, 547; Brown-Séquard, Dr., 334, 415; Browne, Dr. E. A., 408; Browne, Mr. Lennox, 440; Bruberger, Dr., 423; Brügemann, Dr., 824; Brunton, Dr. T. L., 109, 440; Bryant, Mr. T., 87; Buckley, Dr. L. D., 326; Bucknill, Dr. J. C., 769; Buquoy, M., 166; Budde, Dr., 95, 115; Bufalini, Dr., 72; Buhl, Dr., 449, 461, 482; Bull, Dr., 50, 551; Burdell, Dr. E., 297; Burnett, Dr. C. H., 294, 407, 763; Burq, Dr., 43; Busch, Dr., 14, 35; Byrd, Dr. H. L., 665; Byrne, Dr. J., 139
- Babies: rules for feeding (Jacobi), 229
- Baby: cost of, a, 194
- Bacteria: generation and evolution of (Servel), 823
- Balneotherapy, Handbook of (Valentiner), *rev.*, 328
- Balneology, Hydrology, and Climatology, Journal of (Kisch), *rev.*, 329
- Balsam: of tolu and Peru, botanical origin of (Baillon), 217
- Bandages: fixed, removal of (Schinzinger), 179
- Baths: electro-chemical, 187; cold, in fever (Huchard), 795; warm, therapeutic uses of, 800
- Battery: a new (Morin), 344; galvanic-caustic (Voltolini), 764
- Beef: raw, in dysentery, 265
- Belladonna: adulteration of (Holmes), 309
- Bequests: 282, 459, 556, 623
- Berlin: births and deaths in, 186; buildings in, (Strassmann), 682
- Bile: secretion of (Lussana), 47; movements of (Kowalewsky), 260; gasometric analysis of (Boguljubow), 260; spectrum of (Dalton), 514; action of muscarine on (Prevost), 546; action of in promoting absorption of fats (Williams), 712; physiology of secretion (Schmulewitsch), 789
- Bile-ducts: structure of (Asp), 789
- Biliary passages: spasm of (Audigé), 295
- Birds: production of diabetes in (Bernhardt), 294
- Bladder: passage of hairs from (Sewell), 39; cysts in posterior wall of (English), 245; drainage in chronic inflammation of (McGuire), 505; gunshot wound of (Bascieri), 698.
- Blennorrhagia: sulphate of cadmium (Gazeau), 358; spontaneous iritis during (Bergeron), 406
- Blepharadenitis: treatment of (Mooren), 454
- Blood: structure of corpuscles of (Thin), 66; coagulation of (Smeé), 83; numeration of red corpuscles in (Malassez), 132; (Brouardel), 166; transfusion of (Hasse), 166; (Highmore), 171; note on, 202; (Bouley and Béhier), 249; (Kalscher), 392; (Guérin), 453; (Chadwick), 548; (Béhier), 569; (Morton), 630; (Heller), 746; (Thurn), 746; (Brügelmann), 824; (Klingelhöffer), 824; abnormal cells of, in relapsing fever (Ponick), 385; dependence of blood-pressure on quantity of (Müller), 388; intracellular development of corpuscles of (Schäfer), 436; iron in (Jolly), 437; action of chloral on (Feltz), 532; apparatus for transfusion of, 554; diagnosis of stains of (Richardson), 560; dependence of current of on excitation of vaso-motor nerves (Slaviansky), 562; action of gases in coagulation of (Mathieu and Urbain), 711; influence of gaseous contents on solubility of corpuscles (Landois), 729; formation of fibrin from corpuscles (Landois), 729; influence of brain on pressure in pulmonary artery (Badaud), 756; putrefied and septic, experiments with (Robin), 805; poisoning of (Feltz), 806; influence of concentration on changes of form and place of corpuscles (Thoma), 821
- Bloodless operations: (Langenbeck and others), 29; (Esmarch), 275; case of (Valerani), 116
- Blood-vessels: of large intestine (Heller), 226; air in (Kowalewsky and Wyssotsky), 261
- Bone: necrosis of (Heincke), 62; lesion of in infantile syphilis (Poncet), 341; in penis (Lenhossek), 355; gouging and subperiosteal resection of (Seibille), 373; absorption of by giant-cells (Morison), 421; development of (Ranvier), 436
- Bone: temporal, frontal process of (Gruber), 450
- Bones: long, resection of shafts after gunshot injuries (Cousin), 372; normal and pathological growth of (Wegner), 694
- Bone-scraping: in South Sea islands, 220
- Boric acid: antiseptic properties of (Lister), 716
- Brain: Dr. Ferrier's experiments on (Dupuy), 45; (Ferrier) 158; of Agassiz (Wyman), 173; functions of in relation to epilepsy (Dickson), 196; lesions of in general paralysis (Lubimoff), 196; human, experiments on (Bartholow), 285; functions of (Nothnagel), 305; localisation of functions of (Brown-Séquard), 334, 415; of insane, capability of reaction in (Obersteiner), 335; experiments on (Hitzig), 399, 448; ophthalmoscopic appearances of optic nerve in tumour of (Fitzgerald), 406; colloid degeneration of vessels of (Lubimoff), 422; syphilitic disease of (Bruberger), 423; lesion of walls of ventricles in general paralysis (Magnan and Mierzejewsky), 485; physiology of cortex of (Putnam), 525; of tertiary mammals, 608; chemical researches on (Gobley), 630; syphilitic disease of (Jackson), 635; morbid histology of (Major), 661; physiology of (Luys), 680; course of fibres in posterior commissure of (Paulowsky), 729; influence of on blood-pressure in pulmonary artery (Badaud), 756
- Bread: adulteration of (Hardwicke), 121
- Breast: rare form of scirrhus of, in male (Doutrelepoint), 245; cancer of, disease of areola preceding (Paget), 785
- Breath-presentation: difficult removal of head in (Charpentier), 378
- Bright's disease: mania a symptom of (Wilks), 451
- Bromide: of ammonium in catamenial excesses (Black), 506; of camphor, action of (Bourneville), 628; of mercury, action of (Bellini), 157; of potassium, cutaneous eruptions cured by (Neumann), 280, 408; (Veiel), 718; in alcoholic amblyopia (Quaglino), 324; in convulsions of children (Ragland), 358; in gonorrhoea (Bligh), 358; action of (Tommasi), 440; action of (Seguin), 466
- Bromo-citrate of lithia water, 281
- Brontichis: nitrite of amyl in (Kitchen), 264
- Bullet swallowed by a child, 555
- Burrows, Sir George, 124
- Butter: adulteration of, 121, 459
- CALASTRI**, Dr., 226; Callender, Mr., 1; Cameron, Dr. C. A., 182, 279; Cantieri, Dr., 803; Cantilena, Dr. P., 226; Carnus, Dr., 325; Carpenter, Dr. A., 471; Carroll, Dr. A., 490; Carry, M. A., 606; Carville, M., 804; Casa, Dr., 266; Caselli, Dr. A., 246, 323; Cassells, Dr., 621; Cayley, Dr., 823; Cazeneuve, Dr., 486; Chadwick, Dr., 548; Charcot, M., 164, 238, 254, 825; Charpentier, Dr., 378, 676, 705; Chauvel, M., 357; Cheever, Dr. D. W., 505; Chiari, Dr., 199; Chiene, Dr., 668; Child, Dr., 424; Chouppé, M., 503; Christian, Dr. J., 828; Clark, Mr., 563; Clarke, Dr. Lockhart, 386, 516, 730; Clarus, Dr. A., 503; Clemens, Dr. H., 201; Cohn, Dr. H., 607; Cohnheim, Dr., 10; Coles, M., 164; Collin, M. L., 270, 360; Collas, M., 439; Collins, Mr., 563; Colletti, Dr., 452; Colomiatti, Dr., 254, 475; Conner, M. L. M., 264; Coryllos, Dr., 135; Courbès, Dr., 408; Cousin, Dr., 372; Coutinho, Dr., 317; Coyne, M. P., 243; Critchett, Mr. G., 310; Crolas, M., 375; Crombie, Dr., 745; Crothers, Dr. D. T., 528; Crouse, Dr. J. H., 229; Cullingworth, Mr. C. J., 440; Cunningham, Dr. D., 17; Curschmann, Dr. H., 110; Curtin, Dr., 812; Cutter, Dr. E., 378; Cyon, Dr., 36; Czermak, Dr., 437; Czerny, Dr., 142, 145, 160
- Cadmium: sulphate of, in urethral blennorrhagia (Gazeau), 358
- Cæsarean section: application of elastic sutures to uterus (Valentinotti), 73; after death (Rota), 73; cases of (Ungarelli), 118; (Schurig), 519; (Mayer), 735; (Jacobs), 748; closure of uterus by sutures after (Veit), 377
- Calculi: unsuspected, in bladder (Foster), 827
- Calculus: renal (Cayley), 823
- Callous mediastino-pericarditis (Cantilena), 567; case simulating (Albutt), 600
- Calomel: saccharated (Battey), 180; subcutaneous injection of, in pneumonia (Formenti), 537
- Calumba: starch granules of (Pocklington), 102
- Camphor: bromide of (Bourneville), 628
- Camphorated phenol (Bufalini), 72
- Canals: semicircular. See Semicircular canals
- Candles: Field's pulmonary, 312
- Cannibals' tastes, 607
- Cancer: treated by condurango (Friedrich), 85; of uterus (Spiegelberg), 200; of male breast (Doutrelepoint), 245; of rectum, linear rectotomy in (Verneuil), 373; of cervix uteri, treatment of (Goodell), 446; of penis, removed by knife and elastic ligature (Bergonzoli), 452; of stomach, hiccup at commencement of (Eyselen), 601; of penis, recurrent (Maracci), 732; of lower lip (Sayre), 738; of mammary gland, disease of areola preceding (Paget), 785
- Cantharides: physiological action of (Cantieri), 803
- Caoutchouc: electuary of (Varick), 73
- Carbolic acid: treatment of diabetes with (Ebstein and Müller), 84; injection of in hydrocele (Levis), 264; use of, in cheesy pneumonia (Tommasi), 548; as an antiseptic and antimycetic (Lubimoff), 617
- Carbolised resin cloth (Lind), 215
- Carbonic acid: emission of by leaves, 800
- Carburetted hydrogen: formation of in stomach (Schultze), 495; (Ewald), 533
- Cartilage: in the penis (Lenhossek), 325; of nose, reunion of after detachment (Walb), 696; false, in hygroma, treatment of (Volkman), 696
- Cascarella: spurious (Holmes), 309
- Cascan: characters of (Béchamp), 437
- Castor-oil: palatable drink of (Bond), 249; how to disguise, 264
- Cat: transference of ringworm from a (Michelson), 407
- Catamenia: excessive, bromide of ammonium in (Black), 506
- Cataract: treatment previously to operation (Critchett), 310; extraction of (Keyser), 406
- Catherising larynx in croup and diphtheria (Hüttenbrenner), 666
- Cautery: actual use in myelitis and toricollis (Busch), 14; multiple, nevus treated by (Tillaux), 14; electric, in uterine surgery (Byrne), 139; galvanic compared with electrolysis (Beard and Rockwell), 324; galvanic, treatment of callous stricture of urethra by (Gasparrini), 733
- Cellulitis: pelvic (Goschler), 376
- Census: medical statistics of, 150
- Cephalotripsy: extraction by (Huber), 520
- Cerebro-spinal meningitis (Upham), 350
- Chameleon: mechanism of change of colour in (Bert), 172
- Champer, Dr. S., 736
- Chauffard, M., and the Parisian medical students, 751, 799
- Chemicals, proposed regulations for storing of in metropolis, 345
- Chemistry: relation of to therapeutics (Griffiths), 809
- Chest: physical examination of (Wilks), 189, 208; treatment of affections of by rest (Roberts), 403
- Child: amputation of tongue in a (Caselli), 323; coccygeal tumour in a (Wernich), 372
- Children: cerebral pneumonia in (Roser), 14; spinal paralysis in (Bernhardt and Westphal), 61; Nestlé's food for (Ehrendorfer), 70; ulcers of stomach in (Rehn), 70; temporary paralysis in (Frey), 83; diabetes mellitus in (Hirschsprung), 95, 114; (Budde), 115; (Schoubroe), 116, rare kind of leucemia in (Gallach), 130; lithority in (Oppizzi), 229; dislocation of the radius in (Winter), 374; aphasia in (Clarus), 503; ipeacahana emetata in cholera of (Boudon and Chouppé), 503; enlarged thymus gland in (Finch), 504; mortality of in France, 640; diarrhoea of (Dessan), 664; cholera of (Byrd), 665; symptoms of tubercularisation in (Grange), 666; paralysis of during delivery (Seigmüller), 801, 818
- Chloral hydrate: use of in incipient abortion (Besnier), 41, 167; in tetanus and trismus neonatorum (Von Hüttenbrenner), 70; combination with albuminoid matter (Personne), 100; treatment of varix by injection of (Porta and Valerani), 133; (Tonoli and Scarenzio), 732; traumatic tetanus treated by (Coryllos),

135; (Chauvel and Verneuil), 357; use of in medicine (Liebreich), 149; production of anæsthesia by injection into veins (Ore), 181, 375; (Le Dentu), 404; (Deneffe and Van Wetter), 732; (Warlomont), 753; in premature confinement (Martineau), 376; acute rheumatism treated by (Irwin), 438; action of in blood (Feltz and Ritter), 532; injection per rectum in vomiting of pregnancy (Simmons), 572; in puerperal convulsions (Fanny and Charrier), 685

Chloroform: vehicle for administration of, 264; injection of in tic douloureux (Mattison), 358; (Bartholow), 700; influence of inhalation on fœtus (Zweifel), 395; inhalation of in strychnine poisoning, 454; use of in Schiff's laboratory (Hake), 468; death under influence of, 507; in puerperal convulsions (Peter), 519; treatment of dangerous symptoms from (Heiberg), 668

Cholera: in Europe, 7; injection into veins in (Hayem), 25; copper a remedy against (Burg), *rev.* 43; at Munich, 124, 656; in Upper Silesia, 186; propagation of, 202; in Italy, 249; pathology and treatment of (Murray), *rev.* 330; in Hamburg (Erman), 346; transfusion in (Kalischer), 392; epidemics of in France, 416, 432, 447; use of ammonia in (Declat), 440; diffusion of in Europe (Simon), 464; in Hungary, 476; discussion in International Sanitary Conference on, 478, 493; prophylactic treatment of (Lebert), 595, 617; voice in (Matterstock), 746; in Central India (Townsend), 786

Cholera: infantile, *ipeacacuanha enemata* in (Boudon and Chouppé), 503; treatment of (Byrd), 665

Chorea: new treatment for (Dexter), 439

Choroid: bursting of (Arlt), 258; laceration of (Arlt), 259

Choroiditis: syphilitic (Fournier), 15

Chromidrosis: cases of (Foot), 55; (Hofmann), 281

Cinchona bark: Java (Van Gorkom), 216

Circulation: venous, in lower limbs (Giacomini), 139; nomenclature of, 234

Clavicle: fracture of (Sayre), 276

Climatology, principles of (Taylor), *rev.*, 523

Clinical medicine (Foster), *rev.*, 555

Clitoris: hypertrophy of preputium of (Stümke), 521

Clothing: warmth of, 234

Coal: wet, danger of, 16

Coal-gas: poisoning by (Jacobs), 488; (Taylor), *rev.*, 622

Coccyx: tumour of in a child (Wernich), 372

Cocoa-butter: anointing with in scarlet fever, 751

Cod-liver oil: emulsion of (Rice), 136; (Andrews), 297; phosphorised, 281; emulsion of, 700

Coffee: iodised syrup of, 73; adulteration of, 249; naturalisation of, 266

College: King and Queen's of Physicians in Ireland, licensing of midwives by, 76; Royal, of Physicians of London, regulations of, 576; Royal, of Surgeons of England, regulations of, 576

Colleges, Royal, of Physicians and Surgeons of Edinburgh, double qualification, 580

Colliery district, a, 184

Colloid: blistering, poisoning by (Schwerin), 328

Colostrum: secretion of in a case of mastodynia (Schultze), 811

Colour: dependence of perception of on time (Kunkel), 710; sensibility of different parts of eye for (Raehmann), 711

Combustion: in animal organism (Schutzenberger), 514; spontaneous, 720

Compression: production of anæsthesia by (Le Fort), 477

Condurango: cancer treated by (Friedreich), 85

Conjunctiva: wounds of (Arlt), 462

Consumption. *See* Phthisis.

Contagious Diseases Acts, 428, 688

Convulsions: of children, bromide of potassium in (Ragland), 358; puerperal, treatment of (Peter), 519; puerperal, hydrate of chloral in (Fanny and Charrier), 685

Copper: in prevention and treatment of cholera (Burg), *rev.*, 43; anthracosis among workers in (Proust), 761

Cornea: termination of nerves in (Durante), 35; injuries of (Arlt), 225; modification of trephine for (Warlomont), 309; wart of (Robertson), 311; wounds of (Arlt), 463; deposits of metals in (Heckel), 483; herpes of (Pflüger), 553

Coronership of Central Middlesex, 704

Corpus callosum: absence of without disturbance of intellect (Malinverni), 319

Coryza: abortive treatment of (Proust), 264

Coughing: physiology of (Kohls), 436

Counterirritants, action of (Seguin), 480

Cowfold: drainage of, 279

Cremation: remarks on, 17; committee on, 203; proposed prize on, 298; in Vienna, 539; at Naturalists' Congress, 623; cases of, 638; chemistry of, 756

Croton-oil: inflammation after application of (Cohnheim), 10

Croup: cardiac complications in (Labadie Lagrave), 50; continuous gargling in (Johannet), 181; curability of without emetics (Klemm), 389; catheterising the larynx in (Hüttenbrenner), 666

Croydon: sanitary operations at, 153

Crustacea: hypnotism in (Czermak), 437

Crucivellier, M., death of, 172

Crystalline lens: injuries of (Arlt), 259, 272, 288, 289; rupture of (Fumagalli), 325

Cyst: sanguineous, in dura mater (Barbosa), 565

Cysticerci (Pellizzari and others), 641, 690, 741

Cystoid degeneration of iris (Wecker), 185

Cysts, sanguineous of neck treated by electricity (Amussat), 56; dermoid and hairy, expelled from urethra and rectum (Glüge and Danzel), 340; spermatic, contents of (Caze-neuve and Datterberg), 486; serous, of iris (Hosch and Sarell), 621

DA COSTA, Dr., 760; Dalkiewicz, Dr., 700; Dalton, Dr. J. C., 514; Danis, Dr., 226; Danzel, Dr., 340; Darenberg, Dr., 486; David, M., 647; Day, Dr. J., 141; Debove, Dr., 39; Declat, M., 440; Decroix, M., 545; De la Harpe, Dr., 378; De Latour, M., 501; Delore, M., 211; De Neffe, Dr., 732, 753; Depaul, Dr., 377, 781; De Renzi, Dr., 227; Desprès, Dr., 214; Dessan, Dr., 664; Dew-Smith, Dr., 99; Dexter, Dr. R., 439; Dickinson, Mr. J. C., 654; Dickson, Dr. J. T., 196; Dittmar, M. C., 133; Dobell, Dr., 72, 518; Dobrowski, Dr., 218; Dogiel, M., 253; Doutelepoint, Dr., 245; Drysdale, Dr., 42; Duchenne de Boulogne, Dr., 806; Dufour, M., 378; Duhring, Dr., 408; Dujardin, Dr., 294; Dumeril, M., 157; Duncan, Dr. J. M., 27, 73, 74; Duncan, Dr. Martin, 546; Duplay, M., 633; Dupuy, Dr., 45; Durante, Dr., 35; Duroziez, M., 627; Dyer, Dr. R. F., 519

Deafness: progressive (Weber-Liel), 701

Death: signs of, 205, 221; a certain sign of (Danis), 226

Deaths: registration of, 313

Debility: tropical (Dickinson), *rev.*, 654

Decapitation: of fœtus in utero (Depaul), 377

Deer: disease of, in Prussia, 492

Degeneracy: alleged, of human race, 250

Deglutition: phenomena of, studied by graphic method (Arloing), 743

Dementia senilis (Krafft-Ebing), 827

Demoniacal possession, 623

Dentition: dangers of (Finlayson), 14; second, constitutional relations of (Mulreany), 129

Depressants: cerebral and spinal (Seguin), 466

Dermoid cysts expelled from urethra and rectum (Glüge and Danzel), 340

Deserts as health-resorts, 768

Diabetes: part played by glycosuria in (Lecorché), 32; treatment with carbolic acid (Ehstein and Müller), 84; in children (Hirschsprung, Budde and Schouboe), 95, 141; retinal hemorrhage in (Haltenhoff), 218; sign of commencement of (Follet), 274; production of in birds (Bernhardt), 294; death from acetonaemia in (Berti), 567; treatment of (Balfour), 618; use of mineral waters in (Gubler), 708

Diaphragm: paralysis of after section of phrenic nerve (Alyschewsky), 712

Diarrhœa: chronic, treatment of, 454; phthisical, *ipeacacuanha enemata* in (Bourdon and Chouppé), 503; of children (Dessan), 664; oxide of zinc in treatment of (Puygauthier), 796

Diet: infant (Jacobi), *rev.*, 831. *See* Food

Digestion: in large intestine (Czerny and Latschenberger), 145, 160; artificial pancreatic, gases produced during (Kunkel), 757

Digestive canal: nerves of (Arinstein), 261; foreign bodies in (Lunier and others), 627; (Mignon), 768

Digitalein, 420

Digitals: crystallised and amorphous, 420

Digitals: preparations of (Görz), 420

Dipsomania: prevalence of, 768; distinction from alcoholism, 784

Diphtheria: cardiac complications in (Labadie Lagrave), 50; treatment of (Smith), 265; evulsion of a tonsil in (Letzerich), 564; catheterising the larynx in (Hüttenbrenner), 666; treated by local applications of subsulphate of iron (Nelson), 731

Diplomatic congress, 250

Diseases: specific or zymotic (Wilks), 23; assembling of different kinds of in hospitals, 683

Disinfection: household, 172

Dislocation: double, of foot (Romei), 134; of tibialis posticus muscle (Broca), 179; of femur into foramen ovale reduced after six months (Peitavy), 180; of thumb at metacarpophalangeal articulation (Langer), 247; of crystalline lens (Arlt), 272, 288; of thigh, changes of form in pelvis from (Leopold), 339; of radius in children (Winter), 374; of left elbow outwards (Mollière), 536; of femur on dorsum illi (Mollière), 536; of sacro-iliac synchondrosis (Bille), 605; of elbow, reduced after four months (Barbosa), 717

Dislocations: spontaneous, in ataxic patients (Bergeron), 402

Distortion of crystalline lens (Arlt), 272

District medical officers in Italy, 348

Diverticulum: Meckel's, in two children (Riefkohl), 389

Dog: leucocythæmia in the (Bollinger), 320, 337

Dogma *versus* science, 815

Dog's grass (Rabuteau), 710

Double monsters, 572

Drainage: in ovariectomy (Thoma), 265; in chronic inflammation of bladders (McGuire), 505; of abdomen (Hahn), 762; valuable results of, 507

Dropsies: history of (Brochin), 341

Drosera: fly-digesting powers of, 623

Drugs: business in, 59

Dugong bacon, 16

Dura mater: sanguineous cyst of (Barbosa), 565; primary tumour of (Bizzozero and Bozzolo), 714

Dust: atmospheric, microscopic characters of (Cunningham), 17

Dwarfs: a race of, 28

Dysentery: raw beef in, 265; iced water injections in (Wenzel), 274

Dysmenorrhœa: intercurrent (Fasbender), 362

Dyspnoea: subcutaneous injection of morphia in (Regnault), 794

EARLE, Dr. C. W., 326; Ebers, Dr., 783; Ebner, M., 563; Ebstein, Dr., 84; Edes, Dr. R. T., 324; Ehrendorfer, Dr., 70; Eichhorst, Dr., 13; Eismensch, Dr., 89; Elias, Dr., 776; Ellinor, M., 216; Emmet, Dr., 793, 810; Emminghaus, Dr., 80, 423; Engelmann, Dr. G., 685; Englisch, Dr., 245; Erman, Dr. F., 346; Esmarch, Dr., 271; Espinet, Dr., 528; Ewald, Dr., 533; Ewald, Dr. A. C., 727; Exner, M., 30; Eyselen, Dr. O., 601

Ear: middle, non-suppurative inflammation of (Roosa), 326; hypertrophy of, after excision of cervical sympathetic (Biddier), 389; effect of division of semicircular canals (Löwenberg), 681; anatomy of (Politzer), 757

Eau de Cologne, 364

Eclampsia: puerperal. *See* Convulsions

Eggs: decomposition of (Thomson), 562; new use for, 655

Egypt as a health-resort (Walker), *rev.*, 43; climate of (Stirton), *rev.*, 43

Egyptian medical treatise, 638

Elastic compression (Spantigati), 341

Elastic ligature: operation on fistula in ano with (Schell), 246; amputation of arm by (Grandesso-Silvestri), 698

Elbow: dislocation of, outwards (Mollière), 536; dislocation of, reduced after four months (Barbosa), 717

Electricity: treatment of sanguineous cysts of neck by (Amussat), 56; clinical uses of (Smith and Reynolds), *rev.*, 202; in post partum hæmorrhage (Earle), 326; use of, in treatment of nervous disease (Seguin), 481; treatment of hydrocele by (Rodolfi), 553; effect on spawn of frog (Onimus), 694; excitation of heart in mammals by (Mayer), 822. *See* Galvanic currents and Galvanism.

Electro-capillary phenomena: influence of albuminoid substances on (Onimus), 211

Electro-chemical baths, 187

Electrolysis compared with galvanic cautery (Beard and Rockwell), 324; in treatment of stricture (Newman), 473; of base of malignant tumours (Beard), 474

Electro-surgery (Rockwell and Beard), *rev.*, 202

Elephantiasis : of leg, ligature of femoral artery in (Leisrink), 281
 Embryo : determination of age of, 331
 Emphysema : use of mineral waters in (Gubler), 675
 Empyema : following suppurative hepatitis (Calastri), 226 ; treated by free incision (Boutelle), 826
 Encephaloid disease : of liver in an infant (Crouse), 229
 Encephalon : primary lesions of, and consecutive lesions of lungs (Nothnagel and others), 338
 Endocarditis : ulcerative, with phlegmonous periostitis (Hirtz), 632
 Endometritis : during pregnancy (Landau), 265 ; granular of cervix (Levy), 361
 Endothelium : etymology and use of (Foster), 434
 Enemata : large, use of, 269
 Enteritis : pseudomembranous (Raynaud), 620
 Entropion : operation for (Warlomont), 552
 Epidemic diseases : international commission on, 513 ; period of infection in (Squire), *rev.*, 766
 Epilepsy : saturnine, with psychic disturbance (Leidesdorf), 102 ; forensic significance of (Sander), 103, 286 ; true, diagnosis from hystero-epilepsy (Charcot), 164 ; functions of brain and muscle in relation to (Dickson), 196 ; sweat in (Emminghaus), 423 ; pathology of (Browne), 813
 Epithelioma : retrograde change in (Venuti), 38 ; affecting sympathetic nerve (Colomati), 244
 Epithelium : retrogressive change of cells of, in ovum of rabbit (Slavjansky), 226 ; etymology of (Foster), 434
 Epsom salts : in Spain, 28
 Equilibrium : sense of, in man (Mach), 646
 Ergot : acute poisoning by (Henschel), 622
 Ergotin : aneurism of femoral artery treated by injection of (Plagge), 87 ; treatment of uterine fibroids by injection of (Parvin and others), 506
 Erysipelas : treatment of, 454
 Escharotic : use of the solar ray as an (Goodwin), 180
 Esmarch's method of bloodless operations (Langenbeck and others), 29
 Ethionene (Bernutz), 652
 Ethereal oils : action of (Grisar), 71
 Eucalyptus : action of (Siegen), 71 ; febrifuge qualities of (Burdell), 297
 Eupatoria : American (Bagelow), 547
 Eustachian tube : mechanism of opening and closing (Yule), 99
 Excision : of knee, splint for (Packard), 246 ; of hip, subperiosteal (Sayre), 276 ; of anterior tarsus and base of metatarsal (Watson), 307 ; (Holmes), 330 ; of hip-joint (Wolff), 342 ; of shafts of long bones after gunshot injury (Cousin), 372 ; of scapula (Schneider), 667
 Excitants : cerebral and spinal (Seguin), 413
 Exhibitions : sanitary, 119
 Exostosis : subcutaneous fracture of (Chiene and Maunder), 668
 Exposure : inflammation after (Cohnheim), 12
 Extruterine pregnancy (Bandl), 669 ; peritoneal (Depaul), 781
 Exudations in neighbourhood of female genital tract (Spiegelberg), 237 ; gases in (Ewald), 728
 Eye : injuries of (Arit), 209, 223, 240, 258, 272, 288, 462 ; instruments relating to (Knapp), 217 ; observations on diseases of (Mooren), 454 ; foreign body in (Savary), 687 ; sensibility of different parts for different colours (Raehlmann), 711 ; attitudes in paralysis of muscles of (Giraud-Teulon), 830

Face : multiple disjunction of bones of in a fetus (Petit), 671
 Facial obturator, 639
 Fat : chemical properties and physiological action of (Day), 141 ; action of bile in promoting absorption of (Williams), 712
 Fees : Amsterdam medical club, 76
 Feet : morbid sweating of (Latour and Olivier), 163
 Femur : dislocation into foramen ovale reduced after six months (Peitavy), 180 ; pseudarthrosis of, cured by irritant injections (Bourquet), 213 ; spontaneous fracture of from caries, and reunion (Rosenberger), 247 ; changes in form of pelvis through dislocation of (Leopold), 339 ; dislocations of (Mollière), 536 ; subcutaneous fracture of exostosis of (Chiene and Maunder), 668 ; fracture of, treated by immovable apparatus (Hamilton), 761
 Fever : in Stockwell hospital (McKellar), 347 ; propagation of, 428 ; transmission by milk (Crothers), 530
 Fever : enteric, without elevation of temperature (Vallin), 26 ; hypodermic injection of quinine in (Ravacini), 324 ; communicability of (Haviland), 376 ; acute purulent inflammation of mediastinum in (Fränzel), 403 ; pathology of (Klein), 648, 720 ; cold baths in (Huchard), 795
 Fever : intermittent, gelseminum in (McGaughey), 248 ; eucalyptus in (Burdell), 297 ; mineral waters in (Gubler), 725
 Fever : relapsing (Rabagliati), *rev.* 58 ; abnormal cells in blood in (Ponick), 385
 Fever : typhus, etiology of (Zuelzer), 78 ; (Moore), 327 ; (Guillemin), 593 ; outbreak of, (MacLagan), *rev.*, 654
 Fever : yellow, fatty degeneration of heart in (Smith), 517 ; in Gulf cities, 815
 Fevers, malarial : symptomatic myocarditis and myositis in (Vallin), 531
 Fibrin : formation of, from red blood-corpuscles (Landois), 729
 Fibroid : growths on vocal cords (Lefferts), 334
 Fibroid : of uterus, removal of (Wallis), 230 ; with placenta prævia (Hecht), 230 ; expulsion of (Kaufmann), 378 ; treatment of (Goodell), 445 ; hypodermic injection of ergotine in (Parvin), 506 ; removal of (Sims), 549 ; (Braun-Fernwald), 770 ; (Emmet), 810 ; sub-mucous (Bidder), 811
 Fibroma : of orbit, intrauterine (Perls), 518 ; of abdomen (Gersuny), 697
 Fibro-sarcoma : of neck, removal of (Bottini), 230
 Fibrous ankylosis (Sayre), 737
 Field's pulmonary candles, 312
 Filtration : intermittent, 364
 Fingers : spontaneous strangulation of (Menzel), 421
 Fistula : vesico-vaginal (Ranse), 201 ; in ano, operation on with elastic ligature (Schell), 246 ; anal and urinary, chloride of zinc in (Simbat), 375 ; urethro-rectal after abscess of prostate (Schwarz), 504 ; vesico-vaginal (McRae), 604 ; salivary (Prompt), 634
 Flies : protection of animals from, 44 ; parasitic (Spicer), 93
 Flight : in birds, physiology of (Marey), 148
 Flogging girls, 299
 Flower mission, 412
 Foetus : effect of pressure on head of (Duncan), 73 ; decapitation of, in utero (Depaul), 377 ; effect of inhalations of chloroform on (Zweifell), 395 ; bleeding to death of (Valenta), 653 ; multiple disjunction of bones of face of (Petit), 671
 Food : ash-constituents in (Forster), 31 ; Nestlé's, for children (Ehrendorfer), 70 ; cheap, 140 ; analysis of (Whitmore), 183 ; varieties, etc., of (Letheby), 201 ; treatise on (Pavy), *rev.*, 442 ; of plants and animals (Redfern), 557 ; of infants (Jacobi), 699 ; (Van Wyck), 717
 Foot : double dislocations of (Romei), 134 ; excision of bones of (Watson), 307 ; (Holmes), 330
 Forceps : short, improvements in (Vacher), 490
 Fore limbs : of monometres, comparative osteology of (Martins), 775
 Foreign bodies : in stomach, 266 ; in digestive passages (Lunier), 627 ; (Mignon), 708 ; in eye (Savary), 687
 Fork, swallowing a, 523
 Fracture : of astragalus (Romei), 134 ; spontaneous, of femur from caries (Rosenberger), 247 ; of clavicle (Sayre), 276 ; partial, of tibia in an adult (Menzel), 322 ; of femur, treatment by immovable apparatus (Hamilton), 761

Fractures : treatment of (Stearns), 173 ; in ataxic patients (Bergeron), 402
 France : epidemics of cholera in, 416, 432, 447 ; mortality of children in, 640
 Freezing : inflammation by (Cohnheim), 11
 French affairs, 9, 110, 207, 498 ; view of medical progress, 123
 Frog : innervation of glottis in (Spirò), 263 ; effect of electricity on spawn of (Onimus), 694
 Fuchsin : as an antiseptic, 16
 Fungus, hæmatodes of sacro-iliac synchondrosis, ligature of internal iliac artery in (Oppizzi), 374

 Galactorrhæa : senile (Casa), 266
 Gall-stones : therapeutics of colic from (Pichler), 42
 Galvanic cautery : removal of tumours by (Amussat), 412 ; treatment of callous stricture of urethra by (Gasparini), 733
 Galvanic currents : induced, differences in according to nature of wire (Onimus), 56 ; treatment of asphyxia of infants by (Lauth), 167 ; continuous, treatment of opacities of vitreous body by (Le Fort), 539. *See Electricity*
 Galvanism : in amenorrhœa (Whittaker), 735. *See Electricity*
 Galvano-caustic battery (Voltolini), 764
 Gargling : continuous, in croup (Johannet), 181
 Gases : inflammable, formation of in stomach (Schultze), 495 ; (Ewald), 533 ; (Heynshius), 758 ; action of in coagulation of blood (Mathieu and Urbain), 711 ; in human transudations (Ewald), 728 ; produced during artificial pancreatic digestion (Kunkel), 756
 Gastrostomy : for internal strangulation (Berti), 537 ; indications for (Boinet), 568
 Gaultheria : adulterated oil of (Pile and others), 217
 Gelseminum : in intermittent fever (McGaughey), 248 ; therapeutic action of (Hull), 296
 Genitals : lupus of (Bernutz), 652
 Genito-urinary organs : use of mineral waters in diseases of (Gubler), 691
 Gerhardt's percussion-sign of change of pitch (Weil), 451
 Giant-cells : absorption of bone by means of (Morison), 421
 Glands : acinous, of tongue (Ebner), 563 ; conglomerate, in man (Heynold), 663
 Glasses : smoked (Dobrowski), 218
 Glottis : innervation of in the frog (Spirò), 263
 Glycogen : formation of in liver (Salomon), 727
 Glycogen, 297
 Glycosuria : in diabetes (Lecorché), 32
 Gonorrhœa : bromide of potassium in (Bligh), 358
 Gout : treatment by ferro-benzoate of lithia (Dalkiewicz and others), 700 ; treatment by mineral waters (Gubler), 707
 Graafian follicles : retrogression of (Slavjansky), 370
 Grant, Dr. R. E., death of, 555
 Granulation : histological changes in healing of wounds by (Thiersch), 536
 Gravel : treatment by ferro-benzoate of lithia (Dalkiewicz and others), 700 ; treatment by mineral waters (Gubler), 707
 Gunshot injury : resection of shafts of long bones after (Cousin), 372 ; of bladder (Bascieri), 698

Ophthalmoscopic appearances of optic nerve in cerebral tumour (Fitzgerald), 406
Opium: smoking of in United States, 523; in China, 832; crop of, 768
Orange: fluid extract of peel of (Bond), 216
Orbit: measurement of (Gayat), 218; intra-uterine fibroma of (Perls), 518
Osmic acid: poisoning by (Raymond), 622
Osteomalacia: local, of leg (Czerny), 142
Osteomyelitis: of ulna (Hutchinson), 213
Osteoplastic operation: tibio-calcaneal (Le Fort), 179
Otitis: phlebitis of cranial sinuses caused by (Wreden), 719
Ovarian pregnancy (Von Haselberg), 520; cyst, cured by injection of carbolic acid (Martin), 520
Ovaries: removal of with uterus, 571
Ovariectomy: use of drainage-tube in (Thomas), 265; normal (Thomas), 327; management of pedicle in (Sims), 827
Overcrowding, 428
Ovum: retrogressive change of epithelial cells in (Slavjansky), 226
Oxaluria: permanganate of potash in (Thorne), 392
Oxygen: asphyxia from insufficiency of (Le Blanc), 322; absence of in waters of Artesian wells, 444
Oxyhaemoglobin: dissociation of (Schmidt), 729
Oysters: pepsin in, 44

PACKARD, Dr., 246; Paget, Sir James, 785; Pajot, Dr., 570; Panaz, M., 3, 117; Parkes, Dr., 144; Parona, Dr., 763; Parrish, Dr. J., 749; Parrot, M., 199, 369; Parvin, Dr., 506; Paschutin, M., 80; Pav, M. C., 472; Paulowsky, Dr., 729; Pavy, Dr., 442; Peitavy, Dr., 180; Pellizzari, Dr., 641, 690, 747; Perl, Dr., 295; Perls, M., 518; Perronetto, Dr., 641, 690, 747; Personne, M., 100; Peter, Dr., 21, 118, 194, 519; Petit, M., 671; Pfäfer, Dr., 553; Philbert, M., 759; Picard, M., 804; Pichler, Dr., 42; Picot, Dr., 486; Pierné, M., 310; Pile, Dr., 217; Pirocchi, Dr., 90; Plagge, Dr., 87; Plank, Dr., 59; Pocklington, Mr., 102; Politzer, Dr., 757; Pollard, Dr. F., 516; Poncet, Dr., 89, 341; Ponnick, Dr., 385; Poorten, Dr., 379; Porlezza, Dr., 90; Porro, Dr., 137; Porta, Dr., 133; Prévost, M., 82, 546; Profeta, Dr., 763; Prompt, Dr., 634; Proust, Dr., 781; Prout, Dr. J. S., 264; Putnam, Dr. J., 525; Puygauthier, Dr., 796
Pachymeningitis: in the insane (Christian), 828
Palate, cleft: mechanical treatment of (Coles and others), 164
Pancreas: action of muscarine on secretion of (Prévost), 546
Pancreatic emulsion (Dobell), 72; juice, fermentative action on starch in infants (Korowin), 306; digestion, artificial, gases produced during (Kunkel), 757
Papaya juice: wall, poisoning by, 444
Papaya juice: solvent action of, 671
Paracelsus: on the natural treatment of wounds, 348
Paralysis: of vagus in man (Guttmann), 51; spinal, in children and adults (Bernhardt and Westphal), 61; (Frey), 83; general, of insane, lesions of brain in (Lubimoff), 196, 422; relation of granular myelitis to (Rabenau), 197; rheumatic of larynx (De Renzi), 227; aphasia in (Hanot), 421; lesions of ventricular walls in (Magan and Mierzejewsky), 485; case of (Maclaren), 749; diffuse general spinal (Pollard and L. Clarke), 516; and cutaneous disease (Lancereux), 522; generalised vaso-motor of upper limbs (Sigerson), 566; treatment of by mineral waters (Gubler), 708; of

diaphragm after section of phrenic nerves (Alyschewsky), 712; pseudo-hypertrophic muscular (Clarke and Gowers), 730; subacute diffuse spinal (Frey), 778; equilateral facial with trismus and exophthalmos (Wilhelm), 779; of children acquired during delivery (Seeligmüller), 801, 818
Parametral: tissue and inflammation (Spiegelberg), 237
Parametritis (Spiegelberg), 237
Paramphosis: new method of reducing (Bardinet), 88
Paraplegia: malarial (Beardsley), 748
Paresis: general, pathology of (Browne), 813
Paris: poor law relief in, 283; medical profession in, 524; statistics of life and death in, 784
Paritoid: atmosphere of, 186
Parotid gland: fermentative action of on starch in infants (Korowin), 306
Parotitis: epidemics of, 438
Pasture: serotinus (Huber), 378
Pasteur: M., retirement of, 478
Pathological: and anatomical museum at Padua, 396
Pathology: comparative, and teratology (Larcher), 523; text-books of, 591
Pelvic: cellulitis (Goschler), 376
Pelvis: changes in form of through dislocation of thigh (Leopold), 339; comparative anatomy of, 655; subcutaneous symphyseotomy in contraction of (Piccinini), 786
Penis: amputation of (Julien), 118; cartilaginous bodies and true bone in (Lenhossék), 355; removal of cancer of by knife and linear excision (Bergonzoli), 452; recurrent cancer of (Maracci), 732
Pepsin: in oysters, 44; preparation of (Umney), 308
Percussion-sign, Gerhardt's, of change of pitch (Weil), 451
Pericardium: filling of lymphatics of (Schumkow), 262
Perinaeum: treatment of laceration of (Goodell), 446
Periostitis: acute phlegmonous, with ulcerative endocarditis (Hirtz), 632
Peripleuritis (Bartels), 423
Peritoneum: arrangement of in female pelvis (Spiegelberg), 237; fossae of (Waldeyer), 371
Perityphlitis (Bull), 50
Permanganate: of potash in oxaluria (Thorne), 392
Peru: balsam of, botanical origin of (Baillon), 217
Pessary: new intrauterine (Hartwig), 521
Pharmacy: charitable, 283
Phenol: camphorated (Bufalini), 72
Phosphorus: medicinal uses of (Thompson and others), 5; in melancholia (Williams), 411; toxicological investigation of (Lefort), 558; necrosis caused by (Jager), 793
Phosphoretted resin (Gerrard and Abraham), 215
Phthisis: treatment of, 381; treatment by phosphate of lime and juice of raw meat (Blanc), 440; tuberculosis, and pneumonia (Buhl, Hering, and Friedländer), 490, 461, 482; strapping the chest in (McCracken), 50; ipecacuanha enemata in diarrhoea of (Boudon and Choppe), 503; tuberculous ulceration of anus and buttock in (Martineau), 602; with unconsciousness for fifteen months (Scull), 731; treatment of (Behier), 817
Phylloxyera, the, 539, 608, 655
Physiology: text books of, 590 (Foster), 591
Pig: leucocythæmia in the (Bollinger), 338
Pills: Hampson's sugar-coated, 363
Pinguicula: fly-digesting powers of, 623
Placenta prævia: hæmorrhage from (Duncan), 27; (Charpentier), 676, 705; with uterine fibroid (Habit), 74; (Hecht), 230; maternal circulation in (Delore), 211; ring-shaped (Valenta), 653
Plague: in Mesopotamia and Northern Africa, 444, 527, 799
Plants: respiration and nutrition in, 623
Plastic operations: granulating flaps in (Billroth), 87
Pleura: liquids effused into (Méhu), 469
Plexus chorioides inferior, innervation of (Benedikt), 514
Pneumonia: cerebral, in children (Reisland), 14; subcutaneous injection of calomel in (Formetini), 537; cheesy, use of carbolic acid in (Tommasi), 548; in children (Rautenberg), 666
Podophyllin: for acute rheumatism (Dyer), 519
Poison: alleged cure for, 251
Poisoning: by vanilla-ice (Rosenthal), 173; by strychnine, 313; by blistering colloidion (Schwerin), 328; by medicated lozenges, 348;

- chronic arsenical (Malmsten), 441; arsenical, by wall-papers, 444; by lead (Bergeron and L'Hôte), 488; by coal-gas (Jacobs), 488; (Taylor), 622; metallic, treatment of by mineral waters (Reumont), 509; by osmic acid (Raymond), 622; by ergot (Heuschel), 622; with tobacco, 751; resuscitation after (Böhm), 757
- Poisons : in portal circulation (Lussana), 47; physiological antagonism of (Martin-Damourette and others), 242
- Political : position, medical view of, 91; and social troubles, psychical effects of (Lunier), 442
- Polypiform : vegetations on trachea after tracheotomy (Peter), 118
- Polyp : vaso-pharyngeal (Dumeril and others), 157; osteo-plastic resection of nose for removal of (Karpinski), 391; surgical treatment of (Cheever), 505
- Polypus : uterine, recurrent (Duncan), 74; treatment of (Goodell), 446; double (Mayer), 521
- Polysarcia : treatment of (Philbert), 759
- Ponti, M. Girolamo, will of, 624
- Poor : dwellings of, 186; relief of in Paris, 283
- Port : sanitary authorities, experiences of, 184
- Portal circulation (Lussana), 47
- Porte-topique : new vaginal, 427
- Pregnancy : subcutaneous injection in vomiting of (Atthill), 72; course of severe lung-affections during (Wernich), 171; endometritis during (Landau), 265; ovarian (Haselberg), 520; causes of error in diagnosis of (Pajot), 570; administration of hydrate of chloral by rectum in vomiting of (Simmons), 572; extrauterine (Bandl), 669; peritoneal extra-uterine, diagnosis and treatment of (Depaul), 781
- Preston Retreat, the (Goodell), 739
- Prizes : Riberi, 76; of *Lo Sperimentale*, 92; of Academy of Medicine in Paris, 220; in hygiene of infancy, 313; for destruction of phylloxera, 5, 39; of Royal Lombardian Institute, 719; of Royal Society, 751
- Professional secrecy : 655
- Professors and students, 751
- Progressive muscular atrophy : morbid anatomy of (Clarke), 386
- Prolapsus : of uterus (Goodell), 445
- Propylamine : treatment of articular rheumatism by (Thermes), 375
- Prostate : abscess of followed by urethro-rectal fistula (Schwarz), 504
- Proto-organisms : generation of (Onimus), 515
- Prurigo : ferox (Wigglesworth), 281
- Pruritus : of urethra and vagina (Clemens), 201
- Pseudo-hypertrophic muscular paralysis, (Clarke and Gowers), 730
- Psoriasis : and syphilis squamosa (Duhring), 408; state of Malpighian layer in (Colomatti), 475
- Public health proceedings (Simon), 455
- Public services : disorganisation of, 687
- Puerperal : eclampsia (Peter), 194, 519; women, normal pulse, respiration, and temperature in (Linn), 520; tetanus (Blachez), 550; diseases, prevention and treatment of (Goodell), 739, 754
- Pyometra : cure of (Braus), 298
- Q**UAGLINO, Dr., 324
- Quinine : sulphate of as an abortifacient and oxytocic (Chiar), 199; hypodermic injection of (Ravicini), 324; (Lente), 333; action of on nervous system (Heubach), 712
- R**ABAGLIATI, Dr. A., 58; Rabenau, M., 197; Rabuteau, M., 377, 810; Raehlmann, M., 711; Rafinesque, M., 371; Ragland, M., 358; Ranse, Dr., 201; Ravier, M., 436; Rauenburg, Dr., 666; Ravicini, Dr., 324; Rauth, Dr., 247, 535; Raymond, M., 618, 622; Raynaud, M., 620; Redfern, Dr. P., 541, 557, 558; Reeder, Dr. J. H., 452; Regnault, M., 704; Rehn, Dr., 70; Reich, Dr., 288; Reichardt, Dr., 684; Reissland, Dr., 14; Reliquet, Mr., 620, 627; Remington, Mr. J. P., 181; Reumont, Dr., 353, 365, 509; Revillout, Dr. V., 597, 651; Reynolds, Mr. H. T., 392; Reynolds, Dr. J. R., 202; Rice, Mr. W. M., 136; Richardson, Dr. J., 560; Richet, M., 485; Riefkohl, Dr., 389; Riegel, Dr., 293, 744; Ritter, M., 355, 532; Rivers, Dr. S. M., 776; Rizzoli, Dr., 256; Roberts, Dr. F., 403; Robertson, Dr. Argyll, 406; Robertson, Dr. C. A., 311; Robin, Dr., 794, 855; Rockwell, Dr., 202, 324; Rodolfi, Dr., 535; Roger, Dr. A., 634; Rokitsansky, Dr. P., 293; Rollett, M., 663; Romei, Dr., 134; Roosa, Dr., 326; Rosenberger, Dr., 247; Rosenstein, Dr., 68; Rosenthal, Dr., 173, 198; Rosen, Dr., 14; Rota, Dr., 73; Rzerucha, Dr., 104
- Rabbit : male, lactation by, 220
- Rabies : antidote against, 313; treatment of (Fleming), 453; curability of, 545
- Race : hair as an indication of, 656
- Radius : dislocation of, in children (Winter), 374
- Radziejewski : Dr., death of, 76
- Railway : metropolitan, air of, 556
- Ranula : (Forget), 487; (Tillaux and others), 603
- Rattlesnake : elephantiasis treated by poison of, 220; poisoning by (Rivers), 776
- Receipt : old, 251
- Rectum : dermoid and hairy cysts expelled from (Glüge and Danzel), 340; treatment of cancer of, by linear rectotomy (Verneuil), 393; anaesthesia by intravenous injection of hydrate of chloral in removal of cancer of (De Neffe and Van Wetter), 732
- Rectus muscle : internal, traumatic rupture of (Wecker), 622
- Reflex action : in frog, effect of gradual rise of temperature on (Foster), 93; investigation of (Rosenthal), 198
- Resection : intrabuccal of inferior dental nerve (Mosetig-Moorhof), 275
- Resin : phosphorette (Gerrard and Abraham), 215
- Respiration : first in infants, cause of (Lahs), 306; effects of introduction of volatile substances into air-passages on (Knoll), 710; regulation of animal heat by (Riegel), 744
- Respiratory centre (Gierke and Rokitsansky), 293; organs, mineral waters in treatment of chronic disease of (Gubler), 675
- Restoratives (Seguin), 499
- Retina : hemorrhage in, in diabetes (Haltenhof), 219; injury of (Arlt), 289; hemorrhage in, in connection with cerebral, cardiac and renal lesions (Bull), 551
- Retroperitoneal hernia (Waldeyer), 370
- Retropharyngeal abscess : cured by external aspiration (Lincoln), 621
- Retroversions : of uterus, treatment of (Goodell), 430
- Rhamnus frangula : bark of (Ince), 391
- Rheumatism : articular, treatment by trimethylamine (Peltier), 167; (Thermes), 375; acute, treated by chloral hydrate (Irwin), 438; acute, treatment by podophyllin (Dyer), 519; treatment of by mineral waters (Gubler), 707
- Rhinoplasty : by a new method (Ollier), 373; by double flap (Ollier), 391
- Rhubarb : examination of (Howie), 54; starch-granules of (Pocklington), 102
- Ribs : cervical (Clark), 563
- Rifles : new, action of, on animal body (Küster), 630
- Right-handedness, 715
- Ringworm : transference of, from a cat (Michelson), 407; transmission of (Vidal and Hillairet), 522
- Rokitsansky, Dr., celebration of birth-day of, 124; dignity of Baron conferred on, 363
- Rotation of hand (Lecomte), 681
- Rumination : mechanism of rejection in (Toussaint), 678
- Russia : medicine in, 638
- S**ALOMON, Dr. G., 727; Samt, Dr., 408; Sander, Dr., 103, 286; Sands, Dr., 125; Sarazin, Dr., 779; Sattler, Dr., 621; Savage, Dr. T., 73; Savary, Dr., 687; Sayre, Dr., 276, 377; Scarenzio, Dr., 732; Schäfer, Mr., 436; Schedi, Dr., 91; Scherschewsky, M., 36; Schiess-Gemuseus, Dr., 686; Schiff, Dr., 468; Schlesinger, Dr., 35; Schinzinger, Dr., 179; Schmidt, M. A., 729; Schneider, Dr. R., 667; Schouboe, Dr., 117; Schultze, Dr. F., 495, 811; Schutzenberger, Dr., 514; Schurig, Dr., 519; Schwarz, Dr., 504; Schwerin, Dr. E., 328; Scull, Dr. B. W., 93; Spaggià, Dr., 812; Spiegelberg, Dr., 200, 237; Spürö, Dr., 263; Squire, Dr. W., 766; Stadfeldt, Dr., 773; Stearns, Dr. J. H., 173; Steele, Dr. D. A. K., 748; Steiner, Dr., 390; Steudener, Dr., 112; Steurer, Dr., 621; Stich, Dr. E., 244; Sturton, Dr. J., 43; Stoecker, Dr., 653; Stone, Dr., 630; Strassmann, Dr., 682; Strong, Dr. A. B., 748; Stümke, M., 521; Syme, Dr., 425
- Salicylic acid : antiseptic properties of (Kolbe), 599
- San Miguel : thermal waters of, *rev.*, 459
- Sanitary : organisation in Lower Austria, 92; exhibitions, 119; Acts, amendment of, 184, 405, 424; inspectors in Northamptonshire, 120; conference at Vienna, 477, 493, 513
- Saponin : local anaesthesia from (Kohler), 67
- Sarcoma : mediastinal (Allbutt), 600
- Sausages : use of aniline for colouring, 428
- Scaumony : adulteration of, 800
- Scarlet : extirpation of (Schneider), 697
- Scarlet fever : contagiousness of, 172; anointing with cocoa-butter in, 751
- School of medicine for women, 640, 687; in Paris, disturbances in, 799
- Schools of medicine : London, 581; continental, 609. See College, Hospital, and University
- Schwalbach (Fritze), *rev.*, 282
- Scirrhus : of male breast, rare form of (Doutrelepoint), 245
- Scleroderma : adultorum (Kaposi), 750; maligna (Wolff), 751
- Sclerosis : of spinal cord (Troisier), 39; of nerve centres (Debove), 39
- Sclerotic : injuries of (Arlt), 240
- Scorpion : venom of (Joussot de Bellesme), 657
- Scrofula : use of mineral waters in (Gubler), 673
- Scrotum : discharge of lymph from (Manson), 40
- Scurvy : causes and nature of (Villemain), 631
- Sea-bathing : therapeutic indications for (Gaudin), 796
- Sea-sickness : prevention of (Giraldès), 784
- Semicircular canals : function of (Solucha), 81; effect of division of (Löwenberg), 681
- Senega : starch-granules of (Pocklington), 102
- Sensation : time of transmission to brain, 28
- Sensibility : recurrent (Arloing and Tripiet), 662
- Sensorium : time of reaction of (Exner), 30
- Septicæmia : experimental (Robin), 805
- Sex : determination of in utero (Strong and Steele), 748
- Shoulder : conservative injury of (Böttger), 87; amputation at the (Minot), 214
- Sinuses : of dura mater, inflammation of from otitis (Wreden), 719
- Skin : structure of (Lomsa), 131; eruptions on, from bromide of potassium (Neumann), 280; disease of, with paralysis (Lancereaux), 522; (Veiel), 718; treatment of diseases of, by mineral waters (Gubler); 709; effect of venous obstruction on (Auspiet), 829
- Small-pox : in Leeds (Hall), 311; and vaccination, Prussian report on, 314; (McCann), 347; (Gayton), 380; spread of, 348; in Birmingham, 380; in Stockholm, 299, 476; malignant, pathology of (Neumann and others), 402; propagated by vaccination, 636; in India (Townsend), 786
- Smith : Dr. Edward, death of, 735
- Snake-poison : action of (Brunton and Fayrer), 109; transfusion of blood, 202
- Snake-bites : treatment of, by strong liquor ammoniac (Kleinschmidt), 487
- Sneezing : remedy for (Dobell), 518
- Society : microscopical of Victoria, first general meeting, 16; Medical, of Lisbon, opening of session, 76; Charité Hospital Medical, formation of, 92; Medical Mutual Aid of Lombardy, report of, 108; Royal Medical and Chirurgial, office-bearers, 140; New York, of Neurology and Electricity, 313; Royal, medals of, 751
- Soda-water : lead in, 638, 704; Dr. Lankester's report on, 556, 607
- Solar ray : use of, as an escharotic (Goodwin), 180
- Spain : watering-places in, 348; mediæval barbarism in, 735; ophthalmology in, 816
- Sparteine : action of (Fick), 72
- Specific : in zymotic diseases (Wilks), 23
- Spermatic cysts : contents of (Cazeneuve and Daremberg), 486; colic (Reliquet), 620

Sphygmograph: use of, in clinical research (Hoileau), 137
Spinal cord: sclerosis of (Troisier), 36; (Debove), 39; vaso-motor centre in (Dittmar), 133; conduction of sensory impressions in (Nawrocki), 711; of dogs, functions of lumbar portions of (Goltz and Frensenberg), 787
Spinal: paralysis (Bernhardt and Westphal), 61; (Pollard and L. Clarke), 516; (Frey), 778; congestion (Beard), 275; excitants (Seguin), 413; depressants (Seguin), 467
Spirit-photographs, 524
Spirit-ratation: in British Army (Parkes), 223
Spirits: adulteration of (Hardwicke), 120
Spleen: hydatids of (Rosenstein and Sanger), 68
Stansfeld, Mr., and the Contagious Diseases Acts, 688
Starch: granules of, in jalap, calumba, senega, and rhubarb (Pocklington), 102; adulteration of (Bell), 249
State medicine: proposed certificates in, at Cambridge, 784
Stomach: treatment of diseases of (Leube), 63, 77; ulcers of, in children (Rehn), 70; foreign body in, 266; formation of inflammable gases in (Schultze), 495; (Ewald), 533; (Heynsius), 758; differential diagnosis of diseases of (Reyellout), 597; hiccup at commencement of cancer of (Eyslein), 601
Stomach-pump: improved syphon, 138
Stone age: surgery of the, 672
Strichnia: inhalation of chloroform in poisoning by, 454; action of (Falk), 505
Sugar: in oedematous fluids (Bock), 295
Suicide: and lumbri (Goopta), 502; among the ancients, 752; influence of age on, 752
Sulphuric acid: pure (Siebold), 101
Sulphurous acid: as a disinfectant in cholera (Lebert), 617
Sumach: fluid extract of berries of (Remington), 181
Surgeons' assistants, female, 672
Surgery: text-books, 590; of the stone age, 672
Surgical affections: treatment of, by mineral waters (Gubler), 725
Sweat, epileptic (Emminghaus), 423
Sweden: medicine in, 639
Swimming apparatus, 412
Switzerland: intemperance in, 412
Symphyseotomy: subcutaneous, in contracted pelvis (Piccinini), 786
Synchondrosis, sacro-iliac: ligature of internal iliac artery for fungus hematomas of (Opizzi), 374; luxation of (Bille), 605
Syphilis: treatment by mercurial inunction (Panas), 3; (Guenel), 375; deep ophthalmia during the secondary period of (Fournier), 14; nature and treatment of (Drysdale), 43; obscure neuroses of (Allbutt), 88; intracranial, with intellectual disturbance (Milner), 89; inherited, latent stage of (Eisen-schitz), 89; perverted nervous sensibility in (Faid), 90; myriasis consequent on (Pirocchi and Porlezza), 90; infantile, osseous lesions in (Poncet), 341; constitutional, treatment of, by mineral waters and medicines (Reumont), 353, 365; infantile (Rafinesque), 37; congenital, relative frequency of symptoms in (Woodman), 374; tertiary (Fournier), 404; squamous, diagnosis from psoriasis (Duhring), 408; insanity dependent on (Wilks), 411; treatment by subcutaneous injection of mercury (Cullingworth), 440; hepatic (Lacombe), 668; treatment by mineral waters (Gubler), 724; use of iodoform in (Profeta and Parona), 763; uselessness of mercury in (Watson), 796
Syphilitic: meningitis (Poncet), 89; (Bruberger), 423; insanity (Newington), 104; disease within the cranium (Jackson), 635

A., 5; Thomson, Mr. W., 562; Thorne, Dr., 392; Thurn, Dr., 746; Tillaux, M., 14, 404, 603; Tillmanns, M., 629; Tommasi, Dr., 449, 548, 604; Tomsa, Dr., 131; Tonoli, Dr., 732; Toussaint, M., 678; Townsend, Dr., 786; Trassenard, Dr., 76; Trehyou, M., 700; Tripier, M., 370, 662; Troisier, M., 36, 695; Troitzky, M., 260
Tania, treatment of (Liebig), 472
Tar: Norwegian, antiseptic occlusion of wounds by (Sarazin), 779
Tarsus: anterior, excision of (Watson), 307; (Holmes), 330
Tea: analysis of (Allen), 53; (Wanklyn), 53;

botanical examination of (Greenish), 102; adulteration of (Bell), 249
Tears: physiology of secretion of (Reich), 288
Teeth: eruption of (Baume), 82; action of chemical substances on (Flagg), 307; anomalies of (Magitot), 451; antenatal eruption of (Curtin), 812
Temperature: high, after death, 60; effect of gradual rise of in reflex action in frog (Foster), 98; effects of oxygen on (Naumow and Beljaew), 260; influence of alcohol on (Riegel), 293; at great heights, 655; animal, regulation of by respiration (Riegel), 744; daily range of in India (Crombie), 745
Temporal bone: frontal process of squamous portion of (Gruber), 450
Tensor tympani: tenotomy of (Weber-Liel), 764
Testicle: anatomy and histology of (Von Mihalkovics), 32
Tetanus: of new-born children, treatment by chloral hydrate (Von Hüitenbrenner), 70; traumatic, treated by chloral (Coryllos), 135; (Le Dentu and others), 404; treated by hypodermic injection of atropine (Miller), 248; puerperal (Blachez), 550
Text-books: of anatomy, 589; of medicine, 590; of surgery, 590; of midwifery, 591; of pathology, 591; of materia medica and therapeutics, 591
Therapeutics: past, present, and future of (Farquharson), 700, 492
Thermography: medical (Dujardin), 294
Thermometer: new submarine, 396
Thermometry: physiological (Seguin), 69; medical (De Latour), 501
Thrombosis: of utero-ovarian veins (Spiaggia), formation of (Zahn), 823
Thumb: dislocation of at metacarpophalangeal articulation (Langer), 247
Thymus: enlargement of in children (Finch), 504
Thyroid body: lymphatics of (Nawalichin), 262
Tibia: partial fracture of in the adult (Menzel), 322
Tibialis posterior muscle, rupture of tendon of (Gosselin), 179
Tibio-calcanean osteoplastic operation (Le Fort), 179
Tic douloureux: ice treatment of (Walker), 343; deep injection of chloroform in (Mat-lison), 358; (Bartholow), 700
Tinea: tonsurans, treatment of (Browne), 408
Tobacco: influence of on heart (Adams), 537; poisoning by, 751
Toe-nail: ingrowing (Sayre), 738
Tolu: botanical origin of balsam of (Baillon), 217
Tongue: removal of by modification of Reg-noli's operation (Menzel), 117; cure of tuberculous ulceration of (Buquoy), 166; ampu-tation of in a child (Casselli), 323; extirpation of after ligature of lingual artery (Weichsel-baum), 352; acinous glands of (Ebner), 563
Tonics (Seguin), 479
Tonsil: evulsion of a diphtheritic, 564
Toothache: a remedy for (Smith), 167
Torsion: of blood-vessels (McDonnell), 534
Torticollis: spasmodic, use of actual cautery in (Busch), 14
Trachea: polypiform vegetations in after tracheotomy (Péter), 118
Transfusion: of blood, numeration of cor-puscles in (Prouardel), 166; source of supply of blood for (Highmore), 171; in snake-poisoning, 202; remarks on (Boutley and Béhier), 249; in cholera (Kalischer), 392; mode of performing (Guérin), 453; cases indicating (Chadwick), 548; new apparatus for, 554; in anæmia (Béhier), 569; cases of (Morton), 630; (Heller), 746; (Thurn), 746; (Brügelmann), 824; (Klingelhöffer), 824
Trepine: modification of for cornea (Warlomont), 309
Trepine-wounds: dressing of (Sédillot), 808
Trepining: insanity cured by (Skæ), 103; the mastoid process (Brochin), 323
Trichiasis: repositio ciliorum for (Robertson), 406; operation for (Warlomont), 552
Trichinosis: in Berlin, 108; in Bohemia, 251; outbreak of (Wislienzus), 356; case of, 444; in Nordhausen, 492; in Linden, 784
Trimethylamine: use of, in treatment of articular rheumatism (Peltier), 167; (Thermes), 375
Trismus neonatorum (Von Hüitenbrenner), 70; (Stadfeld), 733
Truss: treatment of varicocele by pressure of (Ravoth), 535
Tuberculosis: and phthisis an inflammation

of the lungs (Buhl, Hering, and Friedländer), 449, 461, 482; in children (Grange), 666; treatment by mineral waters (Gubler), 674
Tumour: fibroid, of uterus, with placenta prævia (Habit), 74; expulsion of a (Kaufmann), 378; treatment of (Goodell), 445; (Sims), 549; hypodermic injection of ergotin in (Parvin and others), 506; removal of (Emmet), 810; submucous (Bidder), 811; fibro-sarcomatous of neck (Bottini), 230; intra-cranial (Lawrence), 273; coccygeal, in a child (Wernich), 372; cerebral, ophthalmoscopic appearances of optic nerve in cases of (Fitzgerald), 406; intrauterine, of orbit (Perls), 518
Tumours: pathology of (Stich), 244; removal of, by thermic galvano-cautery (Amussat), 422; malignant, treatment of, by electro-lising the base (Beard), 474; of vulva, bloodless extirpation of (Verneuil), 604; primary, of dura mata (Bizzozero and Boz-zolo), 714
Twins: similarity in, 124; malformed (Porro), 537; with ring-shaped placenta (Valenta), 553
Typanum: perforation of membrane of (Voltolini), 441; (Bonfante), 441; movable exudation in cavity of (Burnett), 763; teno-tomy of tensor of (Weber-Liel), 764
Typhoid germ: Dr. Klein's researches in, 720

The London Medical Record.

WEDNESDAY, JANUARY 7, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

CALLENDER ON THE RESULTS OF HOSPITAL PRACTICE.*

We commend this interesting record of two years of active practice in the largest and oldest hospital in London to the attention of all those who still believe in the doctrine preached by the late Sir James Simpson, of the necessary unhealthiness of large hospitals which have been long in use. But, irrespectively of its bearing on the question of hospital hygiene, the paper is of considerable original value in regard to several disputed points of surgery. A short *resumé* of a part at least of its contents will be acceptable. In the first place we have the gratifying list of amputations (at page 2), representing a continuous series of 30; viz., 13 of the thigh, the same number of the leg, 1 of the arm, and 3 of the forearm, treated in the same wards by the author and Sir J. Paget, without one death. The indications for operation, and especially the ages of the patients, ought to be given, in order to make this table perfect. No one knows better than Mr. Callender how important an influence the patient's age exercises on the result of amputation, since in a former volume of these reports he has called special attention to this very point. And we can hardly doubt that these thirty amputations were performed under favourable antecedents, such as must often be absent in hospital practice. Still the list is amply sufficient to prove Mr. Callender's point, that there could not have been any pestiferous atmosphere in the institution where such serious mutilations could be repeated thirty times with impunity.

Next we have a very important register (table 3) of the pulse, temperature, and respiration in 100 cases of operation, accident, and disease, during eleven days, to illustrate the phenomena of reaction or overaction, and of shock. The former, in Mr. Callender's experience, has been very slight, even of the severe operations; and the latter almost *nil*. On this subject we may quote as follows.

'It is remarkable how little impression is produced by even the most severe operations. On the day of operation (in each instance performed with the aid of ether or of chloroform), the pulse usually rose towards the evening, but in a few cases there was a remarkable fall, owing to the relief which the patient obtained from the removal of some local source of irritation; for instance, in case 25 the pulse fell from 130 to 96, after an amputation at the thigh for a large sloughing cancer-growth from the fibula. The temperature either rose slightly or fell slightly; as a rule, it was not materially affected. When it rose

the highest it did so from a previously high temperature, as in the three following examples:—

| | | | | |
|-------------------|---------------------|-------|-------|---------|
| Excision of knee, | temperature rose to | 103.6 | from | 101.5 |
| Ovariectomy | " | " | 102.2 | " 101.2 |
| Ovariectomy | " | " | 101.2 | " 99 |

'The frequency of respiration increased slightly.

'The first day after operation the condition of the pulse was very various, although in most cases it rose slightly in frequency. The temperature became a little higher, usually towards the evening, and the respirations were again a little more frequent.

'The second day after operation the pulse rose; the temperature also rose, the highest rise being to 104 from 100, but on this day the respirations fell.

'Pulse, temperature, and respiration became natural after operations on the following days:—

| | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|----|----|
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 |
| 3 | 5 | 4 | 6 | 6 | 6 | 4 | 2 | 1 | 2 | 3 |

Number of Cases.

'Taking all the cases of operation which have been under my care, I never saw anything like a condition of shock which could be measured by any register of pulse, of temperature, and of respiration, and I say the same respecting the next series of cases, injuries; for, except in patients admitted moribund, we never found anything in pulse, or temperature, or respiration, which could collectively be said to indicate shock; so that, whatever is meant by the expression, the condition was so transient that it usually passed off before the cases came under our notice, so far as to leave no trace in the three great signs recorded in Table III.'

Mr. Callender adds some particulars of cases brought into the hospital, after the above was written, suffering to all appearance acutely from shock after an accident, in which nevertheless the pulse, temperature, and respiration were hardly affected; and he refers to another case in which a considerable effect was produced on all three functions by mere mental disturbance. The inference which Mr. Callender suggests would be, that the phenomena of shock are rather due to mental than to bodily disturbance. He points out also a condition which occasionally takes place, to which he gives the expressive name of 'subaction,' the reverse of overaction, in which the three great functions are depressed instead of excited. And he agrees with other observers in dwelling on the importance of this attentive thermometry and note-taking, in estimating the probability of secondary complications (pyæmia, erysipelas, &c.); these, however, have been of course very rare in his experience, otherwise his list of operations would have shown very different results.

These results have, as Mr. Callender has elsewhere also explained, been attained by the careful observance of all those details of treatment which are enforced already by the precepts of all surgical authors (though it may reasonably be doubted whether due care is always given to such observance in the hurry of hospital practice); viz., to careful inquiry into the previous history and general condition of the patient even (and perhaps more especially) before minor operations, in preparing him for the operation by familiarising him with the position he will have to observe, or any detail of treatment which will become necessary (such as strapping, catheterisation, &c.); to not closing the wound till all tendency to oozing of blood is stopped [Mr. Callender, it must be premised, almost always uses torsion as a hæmostatic]; drain-

* *Two Years of Hospital Practice.* By G. W. CALLENDER, F.R.S. From *St. Bartholomew's Hospital Reports*, vol. ix.

age for twenty-four hours to remove the bloody serum which usually oozes after operation; dressing with carbolic oil; and isolation of the wound by the use of a separate camel's-hair brush for cleansing each wound. Mr. Callender also likes to treat his stumps on a splint (a practice very grateful to the patient, which is unaccountably rare in our hospitals) and to swing the splint and ventilate the bed by introducing a tube under the bedclothes, warmth being provided by a hot-water bottle at the foot of the bed. The upshot of Mr. Callender's teaching (and the present writer need hardly say that he agrees with it, since he has often said the same thing) is that, for all that has been proved to the contrary, the results of hospital practice can be assimilated entirely to those of private practice—allowing that well-known sanitary rules are observed—provided the same minute care and deliberation be used in the one case which are usually used in the other. That the circumstances of Mr. Callender's hospital experience have been accidentally and unusually favourable is very probable, but the facts speak for themselves, and are hard to explain on any other than the above hypothesis.

Mr. Callender has no faith in the 'antiseptic' theory, though (as above stated) he uses antiseptics freely in dressing wounds. On this point also it is well to quote his own words.

'From what has been said respecting the dressing of wounds, it will be seen that, in a limited way, antiseptic treatment has been used very generally. Cleansing an accident wound or washing an operation cut with carbolic acid lotion, or with chloride of zinc solution, covering the parts with carbolic oil on lint, and sometimes covering an open sore with balsam of Peru, has been the rule of treatment; whilst over all immediate dressings a thick covering of cotton wool has served the purpose of protection and of warmth-giving, and perhaps has been a help in preventing contamination. But, with these measures, my use of an antiseptic treatment ends; and I have the strongest belief that success in the further management of operation and other wounds is ensured by extreme care and gentleness in the manipulation of the parts, by strict maintenance of rest, and by giving free exit to all serous discharge or matter.

'Thus, whilst recognising the good results claimed for the strict antiseptic treatment, I hold that results quite as favourable can be gained by a plan of wound-dressing which is so far more convenient than that treatment, in that it is more simple—one for the carrying out of which the means are always at hand and available for any emergency.'

We have bestowed so much space on this, which may be called the general part of the paper, that we can only give extracts from some of the more interesting special points which are noticed in it.

On p. 33 the reader will find a representation of an excellent splint for the treatment of fractures of the forearm, by which passive motions of the elbow, both flexion and rotation, can be made without any disturbance of the fractured parts, and thereby the lower fragment of the radius can be adapted to the degree of supination in which the other is placed by the unbalanced action of the biceps and supinator brevis.

On p. 35 is a table of the fractures of the femur which have been under treatment—20 in number—confirming the statement of those who assert that, with all care in management, such fractures as a rule are always followed by some shortening, except in

childhood. In one case only is a cure without shortening claimed in adult life—excluding one in which the fracture implicated the inner condyle only, and where, therefore, shortening was impossible. In the only two cases which happened in childhood, the patient recovered without shortening.

The only other subject which our space allows us to notice, is that of stricture of the urethra; on which, Mr. Callender makes the following observations.

'I agree with some remarks, recently published by Dr. Thiry, respecting the practice of puncturing the bladder, for retention of urine.* Dr. Thiry states that he never knew the stricture which could prevent him from passing a catheter into the bladder. I have never had occasion to puncture the bladder for retention, except in the case of a female who was admitted with retention, consequent upon blocking of the urethra by the growth of a cancerous tumour.

'In all severe cases of retention, no attempt at passing a catheter should be made until the patient has had a warm bath, a full dose of opium, and a purge. If relief do not follow from this treatment, and it almost invariably does follow it, a catheter is passed under more favourable circumstances after such treatment has been employed, and after the patient has been for a time recumbent in bed, than if the attempt had been made when he first applied for treatment. If the patient passes water in or after the bath—and I never knew one fail to do so—even although the bladder may not be thoroughly emptied, it will give him a couple of days in bed, with opiates if needed, before using an instrument. When a catheter is passed, I have it tied in for as long a time as the patient can conveniently bear it, usually for two days, beyond which time it is needless to have it retained. On withdrawing it, no difficulty is experienced, the same day or the day after, in passing a much larger instrument, generally a no. 6 or no. 8 silver catheter. In some cases I find it necessary to dilate the stricture with a catgut bougie before introducing a metal instrument, but in such instances the passage for the urine has been narrowed to an extreme degree, and the cases are not of frequent occurrence.

'It is a point which cannot be too strongly insisted upon, that the operation should not cause the urethra to bleed; if any blood escape through the instrument, or by its side, while it is being passed towards the bladder, it is my invariable rule to desist from the operation for the time.

'Except for the purpose of clinical teaching, I have not used instruments for curing a stricture by splitting it, than which it is my opinion that the treatment by means of dilatation with catheters, as here described, is based upon more sound principles of surgery, and is in its results of greater permanent benefit.

'I have never considered it necessary, or have thought it desirable, to operate upon a stricture by cutting into the perinæum.'

The opinions of most hospital surgeons will, we believe, endorse these remarks of Mr. Callender and those which his colleague, Mr. Savory, has recently made on the same subject. The effect of both is to dissuade that constant instrumental interference which is the rule in stricture, but by which most surgeons must recall (both in their own practice and in that of others) probably along with cases in which the cure has been rendered more speedy, others in

* *La Presse Médicale Belge*, September, 1872.

which a case, which would have progressed steadily to recovery if nature had been more confided in, has been rendered long, painful, complicated, and perhaps fatal, by unsuccessful manipulation during the stage of irritation in which usually patients apply for treatment. A very striking fact connected with stricture is the extreme rarity of finding in the dead body (apart from traumatic lesions) any stricture which is really impassible. In fact, the benefit of leaving a patient alone for a time warm in bed, and under appropriate medical treatment, for some days before introducing an instrument, will be obvious to any one who will try the plan. But the verdict of practical surgeons will differ very much as to the non-existence of strictures in which a catheter cannot be passed, and as to the absence of necessity in any case for perineal section. The present writer has certainly in several cases failed to pass an instrument after the most patient trial of rest, medical treatment, baths, chloroform, and every other known means, and has known the same thing to happen to surgeons for whose dexterity and experience he could respond more confidently than for his own; and he has seen several cases, and operated on two, in which, though no actual or complete retention occurred, yet no instrument could be passed (the patient having been under the successive care of several surgeons); and the health was suffering so much from constant irritation and cystitis, that perineal section was performed, and, as far as could be seen, was urgently indicated. Although, therefore, the general teaching of Mr. Callender on this matter, as on the others which he handles, is doubtless sound and very appropriate at this time when various more or less violent methods of treating strictures have been so perseveringly forced into notice, yet his own individual experience appears to have been unusually favourable. With these few selections, we must leave the bulk of the paper to the attentive study of our surgical readers, which it will well repay.

T. HOLMES.

TREATMENT OF SYPHILIS BY MERCURIAL FRICTION. BY M. PANAS, OF THE LARIBOISIÈRE HOSPITAL, PARIS.*

It is remarkable that treatment by friction was the first employed when the specific properties of mercury were established. Since the introduction of internal medication by Van Swieten (Van Swieten's liquor) medical practitioners have several times returned to external application; having found out the inefficiency of the other method in certain cases. This inefficiency has been insisted on quite lately by M. Fournier, one of the most declared partisans of internal medication. The objections which have been made to the treatment by friction are, first, that it is a dirty method, and disgusts the patient; and secondly, that it exposes them to stomatitis and irritating local eruptions of the skin. With regard to the first of these objections, besides its being of quite a secondary nature in comparison with the importance of the object to be attained—the extinction of syphilis in the individual and the arrest of its propagation in the species—it cannot be maintained when it is seen how the ointment is used in practice.

On the other hand, the greater frequency of stomatitis is a serious objection; and I have therefore paid

great attention to it, and during my residences at the Lourcine, Midi, and St. Louis Hospitals, as well as in private practice and at the Lariboisière, I have succeeded in avoiding stomatitis, or in weakening its effects, in nearly all cases.

All who have witnessed my practice have seen that stomatitis is infinitely less common, and much less serious, than it is during ordinary treatment by pills or mercurialised liquids administered internally. I have often had occasion to give bichloride of mercury internally, and to have frictions made on the same individual during six weeks or two months consecutively, without developing the least trace of stomatitis. I have laid down an axiom, with the object of attaining this result, which will excite surprise at first sight; it is, that we must not combat but prevent mercurial stomatitis.

It is, in fact, a rule with the majority of writers on syphilis to suspend antisyphilitic treatment as soon as mercurial stomatitis appears. This, however, is but a delusive guarantee against the subsequent development of stomatitis of a severe type; experience having abundantly shown us that notwithstanding the cessation of the use of the drug and the employment of various gargles and of chlorate of potash, stomatitis, once developed, makes continuous progress. Therefore, I repeat, we must especially endeavour to prevent stomatitis, and not to cure it. We possess for this object an almost certain and exceedingly simple means. From the first commencement of the treatment, I pay attention to the state of the patient's mouth. I make him have his teeth freed from tartar, his carious teeth stopped or extracted; I then prescribe a strongly astringent dentifrice, which he must use twice or thrice, or even more frequently in the course of the day. I have used the following formula for this purpose with much success.

| | |
|--|-------------|
| Powdered cinchona, extract of catechu, | |
| of each | 15 grammes. |
| Tannin | 2 grammes. |
| Alum | 1 gramme. |
| Essence of peppermint or aniseed, a sufficiency. | |

A no less powerful preventive of stomatitis, and one which of itself is a depurative agent in syphilis, consists in inducing sweating. For this purpose I give my patients one or two vapour-baths weekly, from the beginning of the mercurial treatment; this, besides contributing to the thorough cleanliness of the skin, tends to diminish the virulence of existing or prospective syphilitic eruptions. If the patient be a smoker, I order him to leave off tobacco, or to put a restraint on his use of it; and in all cases I enjoin the patients only to smoke with pipes or mouth-pieces made as long as possible, so as to prevent irritation of the mouth by the highly heated smoke, charged with nicotine. To conclude, with regard to stomatitis, in newly born infants and toothless subjects, stomatitis need not be taken into account in the preparation for mercurial treatment, for it never occurs. The eczematous eruption, sometimes brought out on the skin by the use of mercury, is almost to a certainty avoided by taking the precautions which will be subsequently described.

The objections to the use of frictions are thus disposed of; their superiority over the internal treatment in syphilis is so great, that no comparison between them can be instituted. All the mercurial compounds, and especially the double iodides and chlorides, are caustic, and very irritant even in small doses; so that, when they are administered internally, they

* *Journal de Médecine et de Chirurgie pratiques.*

not only very rarely salivate, but they bring on diarrhoea, gastro-enteritis, gastralgia, and dyspepsia; these are sometimes of an obstinate character, and make it necessary to suspend the treatment, but may still last long enough to be of great detriment to the patient. Everything that has been written against mercury as calculated to deteriorate the nutrition and the bodily health, is only applicable to badly tolerated or too long prolonged internal medication, and not to the external use of the medicine; for as M. Liégeois has established in the case of hypodermic injections of corrosive sublimate, and as I have lately witnessed in the use of frictions, the patients, in proportion as they are saturated with mercury, far from wasting, regain a healthy appearance, and become fat in a very remarkable way. I have known some unfortunate sufferers from gastralgia, and dyspepsia, who could not tolerate an atom of mercury taken by the mouth. Their medical attendants, doubtless ignorant of the curative power of frictions, had given them up without treating them, and they were consequently threatened with tertiary eruptions.

It has been maintained that, as the gastro-intestinal mucous membrane is more adapted for absorption than is the skin, the intestinal canal was the best channel by which to introduce mercury into the system. This, however, is a profound and lamentable error, as I shall proceed to show. And, first of all, what does clinical science teach us on this point? It teaches us that while considerable quantities of pills or of liquor mercurialis may be taken without inducing salivation (that irrefragable proof that the mercury has penetrated into the system) a single friction, made for pediculi pubis without any special care, has sometimes sufficed to bring on intense salivation on the morrow of the second day after the application.

If we reflect on what occurs when the mercurial preparation reaches the stomach, we become enlightened. We know, as a matter of fact, that all mercurial salts become more or less changed into an insoluble chloride; and that this, when brought into contact with an excess of chlorine, may pass into a sublimate in a varying proportion; and this, finally, when in contact with albuminoid matters, of which there are many in the stomach, is likely to form chloro-albuminate of mercury, likewise insoluble. In the midst of all these chemical conflicts, complicated by the quantity, the quality, and the larger or smaller amount of acidity in the food contained in the stomach, can we expect to obtain certainty of results from such a mode of administering the medicinal agent? Certainly not. Besides, the results vary in different persons, and in the same person from one day to another. Whether we do or do not produce salivation or diarrhoea, prompt effect on the constitutional manifestations of syphilis or no influence whatever, all this is, we see, left to the caprice of the chemical combinations which are about to take place in the stomach and intestines, on contact with the food, the gastric, pancreatic, and intestinal juices and the bile, and of the healthy or morbid modifications which these in their turn may present. There is nothing of this kind in external medication, where the action is always in proportion to the dose, and varies only with the limits of the degree of absorption peculiar to each individual. A no less important consideration to be reckoned in favour of this treatment is, that the mercury reaches the circulatory system direct without passing through the portal system and the liver; a passage which is only made to the prejudice of the integrity and the ulterior functions of that important organ. It is a

known fact from M. Orfila's researches, that of all the viscera the liver is the organ in which metallic substances are fixed for the longest time. A last and not less important advantage of the external method is, that it renders possible the administration by the stomach, that organ being left free, conjointly with the mercury, of other drugs often indispensable in the treatment of syphilis; such as iron, cinchona, arsenic, cod-liver oil, and iodine. This compound treatment is above all indispensable when an attack of syphilis of long standing is in question.

Up to this point, I have only replied to the objections which have been wrongly set up against frictions. I will now, however, pass to a considerably more important part of the question, that of the greater efficiency of frictions in comparison with internal treatment. As my colleague, M. Fournier, accurately said in one of his clinical lectures, when speaking of frictions, many things are learnt at one's own cost after leaving the schools. By this he meant that, having been brought up in the notion of the superiority of mercurial pills over frictions, he has since been compelled to give up that belief, to the great advantage of his later patients.

This is precisely what occurred to myself as stated in one of my communications to the Société de Chirurgie in 1867; and I have never ceased to reiterate it in my hospital lectures. The results I have obtained are summed up in the following paragraphs. It would here be impossible to relate them in detail on account of their great number, the cases I have collected from the Hôpital du Midi alone amounting to several hundreds.

Patients treated without any result for many months by proto-iodide or sublimate pills, in doses of from two to four daily, have recovered their health after having undergone a very short course of frictions, viz., from twenty-five to thirty days. Patients having old hypertrophied and condylomatous patches about the anus and in the bursæ have seen them disappear after an average of ten, fifteen, or twenty frictions, and after thirteen days' treatment only. Of course no local treatment had been used for these excrescences, and I challenge any one to produce the same effect in thirteen days with the internal mercurial treatment, and still more without mercury. I say this for the benefit of the anti-mercurialists, who are not satisfied by appearances.

I have chosen mucous condylomata for clinical experiment, because they constitute the most inviolable and incontestably characteristic manifestation of constitutional syphilis; and what is true of the condylomata is the same for all other syphilides, as well as for the tardy or tertiary manifestations in those cases of syphilis on which frictions have effect, even where iodide of potassium has failed, contrary to what is generally taught on this point. I have lately demonstrated this in my practice at the Lariboisière Hospital, in the case of a man having an enormous syphilitic testicle, who after having taken six grammes of iodide of potassium daily during six weeks, without any effect, obtained immediate improvement from frictions. In a second case, frictions alone, without an atom of iodide, sufficed to cure the patient rapidly of his syphilitic testicle. These severe forms of syphilis, and above all, those which attack the bones, the nervous system, the choroid and retina, and the parenchymatous organs, cannot be better or more promptly healed than by frictions; a fact established by many almost unhopèd-for cures which I have obtained by this method. M. Ricord

also follows this practice; and M. Fournier, who has arrived at the same conclusion, says, when speaking of syphilitic retino-choroiditis:

'The serious ocular lesions of which we have just spoken, are far from always occurring in the course of severe attacks of syphilis or of cases of syphilis, with such very marked symptoms as can not be passed unperceived. More than once I have been struck with the contrast between these deep-seated and obstinate ophthalmias and the mildness of the external symptoms; whence I come to the conclusion that it is better to mistrust syphilis and always prudent to treat it, even when it shows itself under the most inoffensive and reassuring form.' To this I add, that we must treat as surely and as rapidly as possible, by frictions. After this quotation, we find it difficult to believe that M. Fournier still persists in giving preference to internal treatment by pills of proto-iodide of mercury in ordinary and apparently mild cases of syphilis; since he himself adds:

'In lesions of so grave a nature, I do not think it is expedient to hesitate in employing specific treatment; we must call in the aid of mercury, and mercury administered in the most active and energetic way possible. Mild measures and the treatment known as "slow extinction," are not admissible in such circumstances.'

The proto-iodide, the sublimate, and metallic mercury, given internally, even in large doses, are, most of the time, inefficacious or insufficient against these manifestations. I have been convinced of this by many failures which I deeply regret, and which I should not have to lament, if I had not been obliged to acquire my own education on this point. Mercurial treatment is the true, the only resource; therefore, away with half measures, with shifts which only result in allowing the lesions to become confirmed and incurable. When deep-seated ophthalmia is present, prescribe frictions without delay, gentlemen; and powerful frictions, containing a daily dose of four, six, eight, ten or twelve grammes of double mercurial ointment, or even more if need be. In cases of deep-seated ophthalmia, I owe to treatment by frictions successes which I do not believe I should have obtained by administering mercury internally. I cannot repeat to you too often, that it is owing to frictions, and to frictions only, that we are able to overcome the secondary affections of the choroid, of the optic nerve, and of the retina.

The superiority of mercurial frictions is incontestable in the treatment of syphilis occurring in new-born infants, where the stomach would reject the smallest dose of mercury. On the other hand, in these cases, syphilis yields admirably to the influence of mercurial frictions, made by preference in the axilla.

I have said enough to show the harmlessness of frictions, and their great superiority over internal medication,—a superiority which many of our colleagues seem not to recognise or not to appreciate at its true value, to the detriment of their patients. If the example of so distinguished a practitioner as M. Fournier, whom I reproach with still being too much a votary of the internal treatment, did not suffice to encourage others to follow this method, I would willingly add, especially as it is just to do so, that in Vienna, in many other parts of Germany and in England, the internal treatment is almost entirely abandoned, preference being given to the external treatment in the form of frictions, calomel vapour-baths, or hypodermic injections, of the sublimate.

The last-mentioned mode of practice also received the sanction of the late M. Liégeois.

This is not the place to seek for the physiological explanation of the great energy of the mercury administered by this method, and still less to determine the manner or channel by which this metal penetrates into the organism. It is not that the elements for such an inquiry are wanting; for, having made convincing experiments on this subject, we possess some important data in connection with it. It is, however, of less interest to pure practice, and I therefore prefer here to pass it over in silence, and to proceed directly to the method of employing mercury in friction.

I use double mercurial ointment of good quality; that is to say, where the mercury is thoroughly reduced so that no globules are visible. The usual dose is six grammes a day. The frictions are made at bedtime, on a limited portion of the body, and on one side only—the calf of the leg by preference, or the thigh, groin, or axilla. It is enough to continue rubbing for from three to five minutes at most. The part is then covered with linen and oiled silk, and the whole is fixed by the aid of a pocket-handkerchief and two or three turns of a bandage, so as not to soil the sheets. To avoid irritation of the skin, the situation of the application should be changed every evening; it is wiped off the next morning, and, if the patient wishes, he may be allowed to wash himself with soap and water.

At all events vapour-baths, of which we have formerly spoken, serve to remove all objections to the method on the part of persons who are very particular in attending to their bodily cleanliness. If there be no reason to the contrary, we continue the frictions for a month or six weeks. We return to the use of mercury whenever fresh symptoms appear. By continuous and graduated treatment of this description we are able, without affecting the general health, to destroy the syphilis at the end of a period varying, in the majority of cases, from six months to two years.

BROADBENT, BRADLEY, THOMPSON, AND OTHERS, ON THE MEDICINAL USES OF PHOSPHORUS.

(Continued from page 802 of last Volume).

Mr. J. Ashburton Thompson contributed 'Some Observations on the Use of Phosphorus in Neuralgia,' to the July and October numbers of the *Practitioner*. He first tried the remedy in eighteen cases, which he classified as follows. 'Acute primary attacks, acute recurrent attacks, and chronic cases.' There were six cases under each head, and, as might be expected, the results in the chronic cases were the least satisfactory. Mr. Thompson remarks that 'in all cases ultimately benefited, relief followed the first few doses.' He thinks the proper range of dose is that given by Dr. Wahlstuch in his *Dictionary of Materia Medica and Therapeutics*, viz., $\frac{1}{20}$ gr. to $\frac{1}{4}$ gr. 'To prescribe less than $\frac{1}{20}$ gr. in the first place is to render its therapeutic action apparently variable or uncertain.' He now invariably begins with $\frac{1}{12}$ gr. every four hours. As regards the mode of administering the drug, Mr. Thompson, in his first series of cases, chiefly used a solution made by dissolving one grain of phosphorus in 242 grs. of alcohol by the aid of heat. He considers this preparation quite as efficacious as, and in some cases more convenient than, the

phosphorus capsules (even those in which the oil has been previously, as recommended by Méhu,* superheated, to prevent after a time the precipitation of insoluble phosphorus), or Dr. Radcliffe's pills, which are made by heating phosphorus and suet together in a close vessel, in the proportion of 1 part to 100, making into 3 grain pills, and coating with gelatine,† or the formula of Soubeiran for a 'potion phosphorée,' which Dorvault considers the best method of preparing phosphorus for internal administration, viz., phosphorated oil (French codex†), 8 parts, gum arabic 8, peppermint water 100, syrup 60; make an emulsion. The formula which Mr. Thompson used in the first reported cases is the following.

| | |
|--|-----------------------|
| Tincture of Phosphorus (made as above) | 3 drachms. |
| Rectified Spirit | 2 drachms. |
| Spirits of Peppermint | $\frac{1}{2}$ drachm. |
| Water to six ounces. | |

The rectified spirit is added to prevent the phosphorus from being precipitated in the hydrated form by the water. He remarks that this formula 'forms an active, efficient, and convenient preparation. It is not quite disgusting, and will be readily taken and well tolerated by those who have begun to experience benefit from the first few doses. It is unstable, and should therefore be supplied to the patient in quantities not calculated to last more than twenty-four hours.' The following is an analysis of Mr. Thompson's first eighteen cases. In the primary acute cases, which all recovered, the ages ranged between twenty-five and forty-six years; in the recurrent acute cases, which also were cured, the ages varied from thirty to sixty years; and in the chronic cases the ages ranged between twenty-four and forty. The varieties of neuralgia were trigeminal, cervico-occipital, cervico-brachial, occipital, and sciatic. Of the six chronic cases three were cured, two relieved, and one was unbenefited.

In his second paper, Mr. Thompson expresses himself as not altogether satisfied with the alcoholic solution of phosphorus used in his earlier cases; partly on account of its instability, but more particularly on account of its producing a very objectionable amount of eructation. These drawbacks, he thinks, are all obviated by the following formula:—

| | |
|--------------------------------|------------------------|
| Phosphorus | 1 grain. |
| Absolute Alcohol | 5 drachms. |
| Glycerine | $1\frac{1}{2}$ ounces. |
| Spirits of Wine | 2 drachms. |
| Spirit of Peppermint | 2 scruples. |

One drachm of this mixture contains $\frac{1}{12}$ gr. of pure phosphorus. This combination possesses little or no phosphoric odour, and, according to Dr. Radcliffe's theory 'that the disappearance of the characteristic odour from a solution of phosphorus is presumptive evidence of the oxidation of the drug,' ought to be inert, but Mr. Thompson's successful results in thirteen patients show that this is not the case. Mr. Thompson has given the phosphide of zinc a trial in six cases. This compound is prepared by bringing phosphorus vapour into contact with melted zinc in an atmosphere of dry hydrogen. Only one half the phosphorus in this substance is said to be available for therapeutical purposes; $\frac{2}{3}$ gr. of zinc phosphide

correspond to $\frac{1}{12}$ gr. of phosphorus, and Mr. Thompson finds this the most efficient dose. The drug may be given in the form of pills, in combination with other substances, e.g. quinine, aloes or strychnia, and these pills are found to keep well. The remedy is not so speedy in its action as the solutions of phosphorus in oil or alcohol. Of the six cases treated with the phosphide there was perfect recovery in two, two were remarkably relieved, one could not tolerate the medicine in consequence of its causing vomiting, and the other found no relief. Mr. Thompson concludes his remarks on this substance as follows:—'It is inferior in power (in neuralgia) to the oily solution or the tincture; while, in point of convenience—for portability, and for combination with other drugs—it is superior to them. In point of cost it stands far above comparison with pills and capsules, which require a special process for their manufacture, while it is not subject to any suspicion of degeneration with age.'

The therapeutic value of sodium hypophosphite in neuralgia has been tested by Mr. Thompson in three cases, and the results have been negative. He administered the remedy in water in doses, varying from 5 to 30 grains, every three hours. Two of the three cases were subsequently cured and one very much relieved by a solution of pure phosphorus. Dr. Anstie's experience of sodium hypophosphite agrees with Mr. Thompson's, while, on the other hand, Dr. Radcliffe has successfully treated four cases of nerve-pain with this drug. Mr. Thompson has found this salt serviceable in cases of extreme debility when given in 5-grain doses, and he believes the remedy 'has a special power of creating appetite. It seems to be a remedy which, to maintain its influence, requires to be given in progressively increasing doses.'

Mr. Thompson has seen benefit result from the administration of phosphorus in two cases of impotence,* from that of zinc phosphide in a few cases of epilepsy, and from that of sodium hypophosphite in cases of obstinate leucorrhœa, accompanied by side-ache. He has also observed striking relief from the use of hypophosphite of soda in some cases of dyspepsia.

In the *Bulletin Général de Thérapie*, May 30, 1873, M. Gubler has an able paper on the physiological action and therapeutical effects of phosphorus.† As phosphorus is a diffusible stimulant of great energy and of dangerous activity, M. Gubler thinks it should not be used in any affection characterised by nervous, circulatory, or trophic excitation, as in tonic and clonic convulsions, contractions, neuroses having a hypersthenic action, diffuse periencephalitis, with general paralysis, phlegmasiæ of all forms, fevers of every kind, exanthematous affections, &c. He thinks that phosphorus can only be regarded as a remedy of great value in paralytic affections; in hemiplegia, paraplegia, amaurosis, and other partial paralyses. His experience of phosphorus as a remedy for impotence is not so favourable as that of Mr. Thompson. He says it is either of no value at all, or its effects are ephemeral. It has been found serviceable in some chronic eruptions of the skin; in paralysis occurring after diph-

* Méhu, *Journ. Pharm. et de Chimie*, vol. ix. (1869) p. 94.

† The phosphorated oil (huile phosphorée) of the French codex is made thus:—Phosphorus 2, oil of sweet almonds 100; dissolve with heat. That of the Prussian codex (oleum phosphorum); phosphorus 1, oil of sweet almonds 80; dissolve with heat.

* In one of these cases, published as cured, a relapse occurred. Vide *British Medical Journal*, November 8, 1873, p. 541.

† An excellent abstract of this paper may be found in the *Practitioner*, for July, 1873.

theria; in that resulting from sulphuret of carbon intoxication, in the so-called rheumatismal and hysterical paraplegia. According to Gueneau de Mussy, Isambert, and Féréol, phosphorus is useful in the treatment of mercurial tremor; 'it is also believed to be so in paralysis agitans, and in the various forms of medullary sclerosis affecting the antero-lateral cords, and above all in sclerosis of the posterior columns' (locomotor ataxy.)

Mr. Messenger Bradley (*British Medical Journal*, Oct. 18, 1873) says that he has found phosphorus quite inert in most cases of melancholia, in impotence, in mercurial tremor, in locomotor ataxy, &c. In this communication Mr. Bradley raises objections to the dose of phosphorus prescribed by Mr. Thompson. He does not consider it either wise or safe to begin with a dose of $\frac{1}{12}$ gr. every four hours. He writes, 'My custom is to commence with one-hundredth of a grain, and gradually increase this by one-fiftieth of a grain at a time, until, if necessary, one-tenth of a grain is taken with each dose. Beyond this quantity, I do not go; as I think that, if the remedy be of use, relief will be obtained by this dose equally with a larger.' The following is the formula he now uses. 'He dissolves ten grains of phosphorus in two ounces of ether, agitating the solution from time to time; and of this solution, one minim (containing one-hundredth of a grain) is administered in an ounce of water with half a drachm of glycerine.' Mr. Bradley states that, in a case of bronchocele, which received no benefit from iodine, phosphorus in doses ranging from $\frac{1}{50}$ to $\frac{1}{20}$ gr., caused a considerable diminution in the size of the gland (*Brit. Med. Journal*, Nov. 29, 1873).

In the *Pharmaceutical Journal* for December 6, 1873, Mr. A. W. Gerrard describes a new solvent of phosphorus, viz., resin, the residue 'of the distillation of turpentine,' which is said to be capable of dissolving 4 or more per cent. of phosphorus. Mr. Gerrard calls this substance 'phosphoretted resin,' which he prepares thus. Take a strong wide-mouthed well-stoppered bottle and weigh it, then melt a quantity of resin sufficient to fill the bottle; let the bottle be warmed, then pour in the resin to nearly but not quite fill the bottle, reweigh, and for every ninety-six parts of resin take four of phosphorus. Now observe that the resin is in a fluid state; if so, add the phosphorus and fix the stopper tightly. Place in a sand-bath previously warmed, and apply heat to 200° C. (392° F.); digest at this temperature, and shake frequently, until the phosphorus is dissolved. Mr. Gerrard gives certain details which it is necessary to observe in conducting the process. The formula which he suggests for the exhibition of the drug is the following. Take of phosphoretted resin (4 per cent.) 25 grains; powdered white sugar, 75 grains; tincture of tolu, a sufficient quantity. Pulverise the resin, mix with the sugar, and form into a mass with tincture of tolu; then divide into twenty pills, each pill will contain $\frac{1}{20}$ gr. The therapeutic properties of the phosphorus appear to be in no way injured or modified by this combination. Mr. Gerrard considers 'the advantages of this preparation to be that it is inoffensive to the taste of the patient, definite and reliable for the prescriber, ready and convenient to the dispenser; and he believes, judging from its nature, it has unlimited keeping powers.'

Before we conclude, we must mention that dangerous symptoms have in a few instances resulted from

the administration of phosphorus in the medicinal doses given above. Dr. Anstie records, in the August number of the *Practitioner*, a case in which a few doses of $\frac{1}{30}$ gr. were followed by slight symptoms of poisoning (*Vide LONDON MEDICAL RECORD*, September 3, 1873). Somewhat similar symptoms were also observed in three cases by Mr. Thompson. Some patients seem to be much more susceptible to the action of the drug than others, consequently it is a wise precaution to recommend all patients immediately to leave off the remedy if it should seem to disagree with them.

The general and special symptoms of poisoning by phosphorus are well described in works on Toxicology; it is therefore unnecessary to give them here.

J. B. BRADBURY, M.D. (Cambridge.)

THE CHOLERA IN EUROPE.

The recent extension of cholera in Europe has been remarkable for the wide scattering of the disease and the comparatively small number of localities within the area of dissemination in which it has become actively diffusive. This extension was the continuation of the outbreak which in 1869 commenced at Kiev, in South Russia, and during the next two years, 1870-71, spread generally throughout Russia in Europe, passed the Russian frontier at several points into West, Central, and East Europe, and became widely distributed in Siberia. In 1872 cholera, still prevalent in parts of Great, South, and West Russia, and Poland, extended into Galicia and Moldavia, crossed the Carpathians into Hungary, and spread westward into Silesia, Moravia, Bohemia, and East and West Prussia. The disease entered East Prussia at Tilsit, at Gumbinnen, and at Lyk; and West Prussia at Thorn, on the Vistula, scattering along the course of the river to its mouth, and extending slightly into the districts of Dantzic and Königsberg. It crossed also the border of Austrian Silesia into Prussian Silesia, descending the valley of the Oder to Oppeln.

Galicia suffered much during this extension, 50,000 cases and 19,000 deaths, according to a local report, founded, it is stated, on official returns, having occurred within seven weeks at an early period of the outbreak. In Hungary the northern and north-eastern counties were mainly affected, and the valley of the Theiss; but in the autumn the disease appeared on the Danube at Buda-Pesth, and later in the year at Neusatz, and cases were reported in Croatia. On the Lower Danube groups of cases occurred at Galatz and Tultcha.

Throughout the winter of 1872-73 cholera prevailed, to a greater or less extent, in the whole of the Austrian provinces named, and probably also in parts of Poland. At the beginning of the spring of 1873 it had become disseminated over all Hungary, and was active in several parts of Galicia and Bohemia; but it is reported to have ceased in Silesia and Moravia. In May, 1873, began that extension which it is the purpose of this article to describe.

Following close upon a re-awakening of activity in Hungary, Galicia, and Poland, cholera in May began to spread from these centres in every direction; or rather, it should be said, in all the districts bordering upon these centres from which there is any information; for of the state of the disease in the neighbouring provinces of Russia nothing is known. It ap-

peared at the beginning of the month in Widdin, on the Lower Danube (where, indeed, cases had been reported in the later days of April). It passed the Italian frontier into Venetia, where in the preceding autumn a quarantine had been established in the hope of preventing the importation of the disease by Italian workmen returning home in large numbers from Hungary. It began to descend the Elbe, and appeared at Dresden on the 19th carried there by raftsmen. It commenced also the descent of the Vistula, beyond the Polish frontier, and appeared at Schillno, on the 22nd, raftsmen being here, as on the Elbe, the carriers.

In June, cholera continued to descend the Lower Danube, the river traffic and the movement of troops playing a conspicuous part in its diffusion. Early in the month it was reported at Rustchuk, later at Silistria and Galatz. It began soon to spread in the districts on both sides of the river, and on the southern side it reached Shumla. A squadron of cavalry moving between Rustchuk and Shumla had several cases of cholera on the way. Passing slowly southwards, into Italy, the disease became more widely scattered in the province of Treviso, and it passed into the province of Venice. In the north-west of Europe, continuing its course along the Vistula, it appeared at Neufahr, at the mouth of the river, on the 15th, and was very fatal there among the raftsmen who had come down the stream. On the 27th of the month it broke out in Dantzic. On the Oder it showed itself, before the close of the month, at Ratibor and Breslau; and as early as the 21st it was present in Hamburg, although the existence of the disease there did not become commonly known until several weeks later. On June 29 cholera certainly existed in Vienna, where, indeed, there had been rumours of cases at a much earlier date.

At the beginning of July the epidemic had become widely scattered along the principal lines of river and railway communication in East, Central, and West Europe; and, as the intensity of the epidemic increased in Hungary, Galicia, and Poland, the scattering became greater. Cholera had now shown itself in East Prussia in several places. It was present along the whole line of the Vistula in that province, and it began to spread into the districts on both banks. The disease appeared in Königsberg on July 6, in Elbing on the 20th, and in Gumbinnen at the same date. On the west bank of the Vistula numerous localities in the districts of Bromberg, Marienwerder, and Dantzic were attacked; and cases occurred in Posen on the 27th of the month. But on the 21st the epidemic had reached Berlin and other localities in the district of Potsdam; and still earlier in the month it had appeared in the districts of Frankfort (July 9), and of Magdeburg (July 15). On July 7 cholera had been reported in Munich.

In the course of July the disease was carried across the Baltic to Helsingborg, a small seaport town of Sweden, on the Sound, opposite Elsinore, and there it caused several deaths, and spread slightly into the adjacent district.

In July, also, the disease, still widening its area, appeared in the city of Venice and in Trieste (July 26). It broke out, moreover, in the province of Brescia, among troops stationed on the Lake of Garda; and it extended into the Province of Parma. Further eastward it showed itself in parts of Bosnia and Servia, along the course of the Save; and it found

its way southward into the district north of Salonica, where, in the following month, it prevailed with some severity in several villages. On the Lower Danube, during the month, the disease spread widely on both the Walachian and the Bulgarian shores. Extending in the Principalities, it was present in Krajova and the commune of Skela in the first week of the month; and cases were reported in Jassy on the 5th. In Bulgaria it travelled to the foot of the Balkan mountains, by way of Berkofitsha, Sofia (July 16), and Samakov, but did not pass them, stopping short at the first station on the line of railway which now connects Philippopoli, Adrianople, and Constantinople.

August was the month of greatest activity of the epidemic, as well in the original centres of infection as in the localities in which it had been disseminated during the year. In this month occurred that wide infection of seaports which most closely concerns this country. Dantzic, as already stated, had been infected in June, and Königsberg and Elbing in July. At the beginning of August cholera appeared at Stettin, and in quick succession Memel, Riga, Cronstadt, and Lübeck became infected. Revel and Pernaue escaped until the month following. On August 12 cholera reappeared in St. Petersburg. The ports of Denmark were not attacked, and those of the Netherlands did not suffer until later in the year. But on August 6 the disease was present in Antwerp; the same day it carried off a sailor in the port of Rouen; and on the 19th it appeared at Havre. Passing to the Mediterranean coast, cholera was reported at Genoa on the same day that the disease had shown itself at Havre; and on August 23 the epidemic attacked Naples.

The next month, September, cholera appeared in Paris on the 5th, in Dordrecht on the 17th, and in Fiume on the 29th. In October, cases occurred in Moscow; a slight outbreak took place at Bergen in Norway; on the 19th the disease was reported in Rotterdam and other parts of the Netherlands, and at the close of the month Caen had become infected. In November cholera appeared in Rome, and solitary cases occurred in Brindisi and Palermo, a prisoner being attacked in the latter city a few days after he had been sent there from a gaol in Naples.

Such is an outline of the distribution of cholera, on the continent of Europe in 1873. England did not escape the infection, and the history of the appearance of the epidemic on our shores is highly instructive. London had four importations of cholera. Late in July a body of emigrants coming from Hamburg, then not known to be infected, arrived at Blackwall, and two were struck down with cholera immediately after landing. Among these emigrants, during their stay in the port of London, twenty-eight cases of sickness occurred, and eight deaths, the greater number of the cases and deaths, if not all, arising from cholera and choleraic diarrhoea. In each of the months of September, October, and November, a case of cholera was brought into London, one of the cases coming from Caen, the others from Rotterdam. The epidemic was imported once into Southampton from the French coast. Liverpool had several importations of the disease. A doubtful importation occurred in July, when several cases of choleraic disease occurred among a party of emigrants who had arrived in Liverpool from Hamburg, by way of Hull. In September there were two undoubted importations into this port. The first instance was that

of a sailor who, coming with other sailors from Havre, had travelled to Liverpool by way of Southampton and London, and was seized with cholera shortly after reaching his destination. The second instance was that of a French barque which, the same month, came into the Mersey from Havre, with the master and two of the crew dying from cholera.

Not less instructive than the history of the transmission of the epidemic to this country is that of its transmission to the Bosphorus. This may be noted here. In July the Turkish Government established a quarantine against all arrivals from the Danube and the Bulgarian ports on the Black Sea at the mouth of the Bosphorus. During that month and the two succeeding months 3,000 persons, or thereabout, were placed in quarantine, and among them there were at the time of landing, or there occurred quickly after landing, half a score cases of cholera. Early in August several of the guards placed over the hospital, and others engaged about the lazaret, were seized with cholera. In addition, a soldier from Shumla, who had been detained ten days in the lazaret, was attacked with cholera in Constantinople the day after he had been set free from quarantine.

The time has not yet come when the mischief done to health and life by the extension of cholera which has here been briefly described can be fully told. The facts as yet are only partially known, but this fragmentary knowledge is not without interest, and it is sufficient to justify the expression of opinion at the beginning of this article, as to the comparatively slight diffusion of the disease within the area of its dissemination beyond the original centres of infection. Of the sickness and mortality from cholera in those centres there is information only as to Hungary and Poland, which, however, it must be observed, requires confirmation. According to a local statement, founded, it is said, upon official returns, there were in Hungary (exclusive of Croatia, Slavonia, and the Military Frontier), from the commencement of 1873 to the decline of the epidemic in October last, 433,295 attacks and 183,549 deaths among an estimated population of 16,000,000. The mortality, indeed, during this period, if these numbers be accurate, was nearly three times greater in proportion to population than that which occurred in London during the outbreak of 1849, and six times greater than that of the last outbreak in the metropolis in 1866. In Poland, during the recent prevalence of cholera, 30,000 deaths are said to have occurred. From May 18 to October 1, 1873, there were in Warsaw 6,125 cases and 2,317 deaths. In the outbreak of 1867 in this city the cases numbered 7,249 and the deaths 2,222; in the outbreak of 1852, during July and August alone, the cases were 10,900 and the deaths 4,700.

The returns for Prussia are not complete. A return dated October 24 gives as the total sickness and mortality caused by cholera in that kingdom, to that date, 38,624 cases and 19,655 deaths. The provinces which had the largest number of cases and deaths were those of Prussia, which includes the districts on the Vistula, and of Saxony, which is traversed by the Elbe. The former province had, to the date given, 10,323 cases and 5,089 deaths; the latter province 9,051 cases and 4,227 deaths. In the town of Königsberg, cholera, which in 1871 had caused 1,562 deaths, in 1873 caused 953 deaths. Stettin, which had lost 1,984 lives from the disease in 1866, lost from it in 1873 only 186 lives. The loss of life

in Hamburg during the recent outbreak was 1,002; in the outbreak of 1859 in this city the deaths were 1,286; in that of 1866 they were 1,021. Antwerp, where the disease is now said to have ceased, had 120 cases and 76 deaths to November 30. There were 140 deaths in Rouen during the seven weeks ending September 17; and in Havre 176 deaths during the ten weeks ending November 7. Paris, from September 5 to November 3, had 524 deaths from cholera. In Vienna 3,283 attacks and 1,466 deaths from the epidemic were reported between July 16 and October 20. Munich had 332 cases and 124 deaths to August 18. The progress of the disease in Italy to the present moment appears to have been free from any marked activity. In Venice there were, from July 8 to August 18, 641 cases and 306 deaths; in Trieste, from July 26 to November 5, 581 cases and 328 deaths. In the province of Parma, from July 24 to October 11, the cases were 397, the deaths 251; in the province of Brescia, from August 1 to October 9, the cases were 419, the deaths 242. The epidemic appears to have been more active in Naples than elsewhere in Italy.

On the Danube, the different towns attacked suffered to a comparatively slight extent. In Bulgaria the disease underwent a notable development in one district only, that of Shumla, where in the city, camp, and surrounding country it carried off, between June 21 and August 6, 1,243 persons. From the spring of the year to November 6, the outbreak in the Principalities caused 8,445 attacks and 3,103 deaths. Of these deaths, 406 occurred in Bucharest.

Cholera has now become dormant, if not extinct, in the greater part of the districts in which it was disseminated during the past year. Slight rekindlings of the epidemic have recently been reported in Berlin and Munich, and occasional cases still occur in the Netherlands. Although apparently dying out, the disease has not yet ceased in Hungary, and probably in other provinces of the Austrian Empire. Whether cholera will again become active in Western Europe this year it is impossible to say. We know that the infection of the disease has been widely scattered. We know, also, that the local conditions which are necessary to the growth of the infection abound. Anything beyond this must, at the best, be an ingenious guess. We do not know what constitutes a good cholera year, any more than we know what constitutes a good potato, or a good turnip, or a good wheat year, and we cannot foretell either the one or the other.

FRENCH AFFAIRS.

(From an occasional French correspondent.)

I am sorry to say that our debates at the learned Societies here, and the articles in our journals, are not much improved in international courtesy or in cosmopolitan sagacity. We are still as much irritated by the communication of any progress made by the Germans, and as little conscious of the achievements of the surgical world in general, as we were before; and we have not yet learnt the necessary lesson, that there is a world of science outside France, and that it does not always come to school here. I know your Gallic tendencies, and the tenderness which you show to Gallic weakness. I am sure that it is not exaggerated; at any rate you must always remember that we take all your compliments *au pied de la lettre*, and promulgate the flattery of your after-dinner

speeches, as a gospel of homage to French superiority. As an Anglo-Frenchman with one foot on each side of the channel, I permit myself to be rude, cynical, and *narquois*.

As your journal is now read and quoted more than any other foreign journal on this side of the channel, I hope I may be permitted, as your occasional correspondent, to say how things appear to me here; and if my French colleagues deign, as they sometimes have done in my past letters, to notice this, I would ask them to consider it as a wholesome bitter belonging to the *régime tonique*, which is coming much into use here, with other of your worn-out clothes. I was not a little amused lately, after reading the address of Dr. Parkes, to hear a discussion on typhoid and typhus at the Académie de Médecine here, in which the capital distinctions between the two diseases were on the one hand suppressed, and on the other re-established imperfectly, without knowledge of, or reference to, the classical, complete, and splendid studies of Stewart, Jenner, and Murchison—classical and standard everywhere except in our unhappy France, where we really live in a sort of addled egg-shell.

It was curious too to hear, more lately still, M. Verneuil, M. Lannelongue, and M. Guyon discussing, at the Société de Chirurgie, the 'bloodless method of Esmarch,' which that terrible traveller, M. Demarquay, had brought us back from his trip to Vienna. M. Verneuil acted as master of the ceremonies to introduce his colleagues; and they, ignorant that the habit of elevating the part to be removed and applying arterial compression has for years been practised by surgeons in Edinburgh and in London—and ignorant of what has been published on the subject in the British journals by Mr. Erichsen, Mr. Clover, Mr. Lister, and Mr. Mac Cormac—described this as a French novelty of a year old! M. Verneuil repeated, with an air of ingenuous originality, as counter-indications, those which Esmarch himself has carefully pointed out in his lecture in *Volkmann's Sammlung*; and at last M. Demarquay had gravely to vindicate his intelligence as a traveller by reminding his audience that the matter of priority was the simultaneous arrest of venous as well as of arterial hæmorrhage. But in truth, besides this ignorance of the progress of the medical sciences and practice in Europe, which is due largely to our fatal ignorance of European languages, there is a habit of incessantly abusing the Germans, which might well be left to the political papers, who acquit themselves in the matter with infinite grace and untiring vivacity. There is no reviewer, no *feuilletoniste*, no writer of paragraphs, who does not vent his little sarcasm at the 'mysticism,' the infidelity, the errors, the wordiness, the false doctrines, and the conceit of the Germans. If they would only believe that every one is persuaded of it, and cease trying to convince each other! But it is endless, and pervades every debate.

At the recent *séances* of the Société de Chirurgie, M. Trélat distinguished himself by a *chaleureuse allocution* on the surgical treatment of the necrosis of the jaw due to phosphoric poisoning, in which he advocated the ordinary rules of surgery, and described the practice well known to all British surgeons. Whereupon, M. Verneuil congratulated M. Trélat, and declared that he might 'boldly pose himself as the head of the file of the French school against the doctrines of the German school.' Surely it is time that this silly declamation against the *sol*

maléant of Germany should cease; it is degrading to our scientific character as Frenchmen. We ought by this time to have sufficiently recovered our self-possession to be able to discuss scientific doctrines without regard to their 'soil,' and to cease to betray a soreness which we should then the sooner cease to feel. The incessant abuse of Germany in our scientific debates is, I fear, the surest way to alienate the respect which we desire to have from the rest of Europe. A majestic ambition is far removed from these tricks of wounded vanity. This Allemanophobia resembles a little too much the ancient declamations against *la perfide Albion*. A nation ought to consider that it may sometimes be in the wrong, and that to persist in attributing eminence to impudence, is almost as foolish as the insensate determination to palliate defeat by the allegation of treason.

Some of us hoped much from the *Revue des Sciences Médicales* of M. Hayem, which began its career at the commencement of 1873; but, although able and useful, it is heavy, slow, and appears in too great bulk, and at too long intervals. We want something short, sharp, pithy, and critical, giving us a digestible weekly meal, like the *Centralblatt* or the LONDON MEDICAL RECORD. I really think, indeed, it would answer the purpose of one of our publishers to translate the latter paper, and republish it here weekly. I think it would have a fine sale at once, and after a time it would have a very great sale, for it is more wanted here than with you.

We are going to have a new medical journal, the *Journal de Thérapeutique*, edited by M. Gubler, a famous therapist; and I trust it will be a little more cosmopolitan than our other journals are. Ferrier's researches are hardly known here yet, but I am told that they will presently be translated and published with a preface by Charcot; and it will be odd if they are not proved to have French antecedents, as M. Broca has shown to his own satisfaction to be the case with Hunter's treatment of aneurism by distant ligature, and Bellingham's treatment of aneurism by pressure.

PATHOLOGY.

COHNHEIM ON INFLAMMATION.*

(Continued from page 822 of the last volume.)

B. *Inflammation after the Application of Croton Oil.* The same set of appearances as already mentioned as being characteristic of acute inflammation, take place after the application of a drop of very diluted croton oil (one drop to twenty-five or thirty drops of olive oil, or of glycerine, on the tongue of the frog prepared as in the first experiment). The reagent is allowed to stay there for five or ten minutes, after which time it is wiped off. (A stronger mixture, or even this diluted mixture, acting for more than ten minutes, quickly produces complete stasis in the blood-vessels.) Immediately after the application of the above mixture, an enormous dilatation with increased velocity of the blood-current ensues in all the vessels of the injured parts. This condition of the vessels lasts for several hours. Gradually the circulation becomes slower, without, however, the vessels having become contracted, as in the former

* *New Researches on Inflammation.* By JUL. COHNHEIM. Berlin. 1873.

experiment. This decrease in the circulation commences in the superficial capillaries, in some of which it comes even to stasis, and extends to the veins, and finally also to the arteries. As soon as the circulation has become slower, the characteristic adhesion of colourless corpuscles takes place in the veins. This is soon followed by extravasation of only coloured corpuscles from capillaries, and of coloured and colourless corpuscles from capillaries with decreased circulation, whereas from the veins only colourless corpuscles extravasate. The number of capillaries with stasis gradually increases, and after twenty-four hours the circulation has also ceased in several veins, their contents being now arranged in a very characteristic manner, viz., coloured and colourless corpuscles being arranged in longitudinal sections corresponding to the previous adhesions of colourless corpuscles to the wall of the vessel. This represents the *itio in partes* of Samuel (see *Virchow's Archiv*, vol. xl.) It must be added that, as soon as stasis appears in the veins, there is an end of all extravasation and transudation. If a few drops of croton oil be rubbed over the inner and outer surfaces of the shaved ear of a white rabbit, no variation whatever is to be observed on the vessels during the first hour. After seventy or eighty minutes, however, a slight trace of general redness is to be observed; while at the same time the outlines of the vessels lose much of their sharpness and distinctness when inspected with the naked eye. The redness and swelling of the ear become gradually more marked; but, even two hours after the application of the croton oil, the characteristic normal pulsation of the arteries is still very distinct, and also in the veins there is no irregularity to be noticed. After one or two hours later the ear is extremely red and swollen, and very hot, and at the same time numerous small red specks and lines are observable, which are nothing else but hæmorrhagic points in the cutis as well as in the subcutaneous tissue. All these symptoms increase in their intensity during the next twenty-four hours. With the second day the process becomes again retrograde, generally with desquamation of the epidermis. In about four or five days the ear has returned to its normal condition. The microscopical examination of sections through the ear at different stages of the inflammatory process, proves that there is no abnormality as long as the ear does not show microscopically any abnormality; that the first swelling is due merely to exudation of an albuminous fluid, and that, as long as the process increases in intensity, the tissue of the ear becomes more and more infiltrated with emigrated blood-corpuscles, the superficial parts of the cutis, the tissue surrounding the hair-follicles and the loose subcutaneous tissue at the root of the ear-lobe being always most infiltrated. It is evident from this experiment that the dilatation and hyperæmia with increased velocity of the blood-current, immediately following irritation, do not necessarily belong to the series of the typical phenomena of an acute inflammation, but that these latter develop gradually, independently of any reflex mechanism, and that they are due to a gradual alteration of the wall of the vessels; for the whole series of phenomena invariably take place, not only if the sympathetic nerve of the neck have been cut through previously to the application of the croton oil, but also if the whole ear-lobe be placed in a ligature, with the exception of the median auricular artery and vein.

The assertion of Samuel that in the inflammatory

process stasis takes place in the veins, whence an impediment is established, the consequence of which is an intensive exudation of fluid and of corpuscles from the blood, is contradicted by Cohnheim, who maintains that such a stasis in veins during inflammation does not happen at all; for, if the veins of the inflamed ear-lobe be opened next to the inflamed parts, the blood flows from them drop by drop, exactly as in a normal ear-lobe.

C. *Traumatic Keratitis*.—In every case in which, after an injury of the cornea, the tissue of the latter becomes infiltrated with more or less numerous pus-corpuscles, an alteration has preceded in the vessels of the conjunctiva next the cornea, consisting chiefly in the very marked injection of the vessels. That this injection of the conjunctival blood-vessels is not the result of reflex action, can be proved, first by the fact that traumatic keratitis is very much favoured by cutting the fifth nerve, and secondly, by the following experiments. In a rabbit in which the facial nerve has been cut in order to avoid the frequent movement of the eyelids, a portion of the cornea two or three millimetres ($\cdot 078$ to $\cdot 118$ inch) in diameter is scraped off with a lancet-shaped knife; or the cornea is cauterised over a very small region with lunar caustic, care being taken that the caustic does not come into contact with the conjunctiva; or finally, the cornea is cauterised with the knob of a red-hot probe. In all these experiments, generally no injection of the vessels of the conjunctiva ensues, and the cornea remains perfectly transparent all round the injured part.

In those cases, therefore, in which, after an injury of the cornea, an injection of the conjunctival vessels does ensue and a subsequent opacity extends from the periphery towards the injured part of the cornea, there must be some other factor which produces that alteration of the vessels of the conjunctiva; it being proved by the experiments just mentioned that it cannot be due to a reflex action following irritation of the sensitive nerves of the cornea. Cohnheim takes it as very probable, that, in consequence of the traumatic injury, septic agents, produced by certain changes of the tissue, probably chemical changes, gradually extend from the seat of the injury towards the periphery until the vessels of the conjunctiva are reached, in the walls of which they produce an alteration, which gradually increases. The effects of this alteration are the above-mentioned injection of the vessels, and the subsequent infiltration of the cornea with pus-corpuscles. With this assumption agrees very well the fact that, after traumatic injuries which produce keratitis, the injection of the vessels of the conjunctiva, which is always the first symptom, does not immediately follow the injury, but takes always some time for its development. The very immediate conjunctival hyperæmia in man observable after a traumatic injury of the cornea, is to be accounted for by the very vehement rubbing of the eye, and the increased and energetic movement of the eyelids. If however in a rabbit, whose facial nerve has been cut through, keratitis be produced, e.g. after inserting a fine silk thread in the centre of the cornea, there is nothing abnormal to be noticed in the first hours; in the third or fourth hour conjunctival hyperæmia is observable which gradually increases, its acme not being reached previous to the twenty-fourth or thirty-sixth hour.

D. *Inflammation by Freezing or Heating*.—Abnormally high or abnormally low temperatures, not exceeding $+44^{\circ}$ Cent. or -4° Cent. (110° or 24.8° Fahr.), have no effect whatever on the circulation of the

tongue or of the web of the frog. Still higher degrees (50° Cent. 122° Fahr.) or still lower degrees (-7° or -8° Cent. = 19.4° or 17.4° Fahr.) produce a gradual decrease of the circulation, until finally absolute stasis is established, without any extravasation or transudation.

Better results are obtained on the ear of the rabbit. The ear is dipped into a vessel containing either a freezing mixture or hot water, where it is kept for a variable time according to the will of the experimenter. An ear which has been frozen stiff in a freezing mixture thaws when taken out again the more slowly, the longer the period during which it had been kept frozen, and the lower the temperature of the mixture. Very shortly after it thaws, its vessels become again filled from the arteries; the vessels dilate and the circulation in them goes on with great rapidity. If the temperature of the freezing mixture have not been lower than -6° Cent. (21.2° Fahr.) no other effect is produced, even if the ear have been kept at that temperature for a considerable time, for the vessels contract again and the ear assumes its normal appearance.

If, however, the temperature have been -7° Cent. or -8° Cent. (19.4° to 17.4° Fahr.) then the hyperæmic ear becomes swollen; it assumes a rosy colour; the swelling however does not increase very much, and in one or two days disappears again. If the temperature have been -4° Cent. (6.8° Fahr.) then the swelling is very marked, the ear becomes very hot, the swelling does not disappear so quickly and there is generally desquamation of the epidermis. If the temperature have been -15° Cent. or -16° Cent. (5° or 3.2° Fahr.) there is always suppuration in the depth of the ear, sometimes also partial necrosis. This latter is generally the case if the temperature have been -18° or -20° Cent. (-0.4° or -4° Fahr.) for then there are always excessive hyperæmia and hot swelling, which is followed by suppuration; the epidermis becomes detached in the course of the process in greater or smaller parts, and after two or three days the apex or various parts of the ear become necrotic. On microscopical examination, it is found that the swelling occurring after -7° Cent. or -8° Cent. is due to simple œdema. If the temperature to which the ear has been exposed have been still lower, the tissue of the ear is found to be infiltrated with pus-corpuscles, the number of which is the greater, the lower the temperature was and the longer it acted. The most numerous pus-corpuscles are to be found in the loose tissue at the root of the ear-lobe, then in the inner parts of the ear and in the neighbourhood of the cartilage.

Very similar are the appearances which follow abnormally high temperatures, lower degrees of heat 48° Cent. to 40° Cent. (118.4° to 120.2° Fahr.) producing simply œdema, higher degrees 50° Cent. + 53° Cent. (122° to 127.4° Fahr.) distinctly inflammatory changes; and still higher degrees, as 58° Cent. or 60° Cent. (136.4° or 140° Fahr.) producing more necrotic changes.

From the nature of these changes, and from the fact that ligaturing the ear with the exception of the median artery and vein previously to the application of the extreme temperature does not affect the result of the experiment, it is clear that it is to the vascular system these changes must be referred. That it is not the action of the extreme temperature on the blood itself which produces those changes, can be proved by emptying the vessels of the ear of their blood by injecting through them a 75 per cent. saline

solution, and then subjecting the ear to the extreme temperature; when after the experiment, blood is again allowed to enter the vessels, exactly the same appearances ensue as in an ear the vessels of which have not been emptied of their blood. It remains, therefore, only to refer those changes to the walls of the vessels having been altered by the action of the extreme temperature.

E. Inflammation after Exposure.—The appearances after exposing the mesentery or the wounded tongue of the frog to the atmospheric air have been fully described by Cohnheim in his former paper, (*Virchow's Archiv*, vol. xl.) where it was mentioned that first the arteries and then also the veins dilate, and that only the veins remain permanently dilated; farther that the velocity of the blood-current is at first generally increased but becomes gradually slower after a longer or shorter period, while at the same time colourless corpuscles become adherent to the wall of the veins; and finally, that a coagulable fluid exudates from the blood-vessels, together with colourless blood-corpuscles from the veins and coloured ones chiefly from the capillaries. The cause of these appearances must be looked for also here in the alteration of the wall of the vessels by the action of the atmospheric air. Whether this action lies in the air conveying the germs of organisms or not remains to be proved.

The hypothesis that, in the different inflammatory processes mentioned in the foregoing, the alteration of the wall of the blood-vessels represents the cause of all those symptoms that form the inflammatory process is supported by the following facts.

1. Obnoxious agents acting on the wall of the vessels exclusively, without coming into direct contact with other parts, produce all the symptoms of inflammation. To illustrate this, Cohnheim ligatures the ear of a rabbit at its base, with the exception of the median artery and vein; by allowing to pass through the vessels of the ear a weak saline solution, the vessels are emptied of their blood, and can be filled then with any obnoxious fluid which is allowed to flow out again through the vein. After all the remains of that fluid are removed by repeated injection of saline solution, the blood is again allowed to enter the ear. In this way Cohnheim found that pure diluted saline solution had no obnoxious effect whatever; that, after the injection of perfectly fresh serum of the blood of the dog or ox, the ear remained healthy in almost all cases, whereas, after the injection of distilled water, albumen of egg, serum of dog's blood, which contained traces of acetic acid or ammonia, especially diluted alcohol or ether, weak emulsions of oil of turpentine or croton oil, atmospheric air or even pure olive oil, which is allowed to remain in the vessels for a short time—either a typical inflammation ensues, often followed by a partial necrosis, or a smaller or greater part of the ear becomes at once necrotic.

2. It had been shown by Cohnheim in a former paper ('Researches on the Embolic Processes,' Berlin, 1872), that the temporary exclusion of the blood from a vascularised area is followed by changes which are probably due to a degeneration of the wall of the vessels, these changes being proportional to the duration of the exclusion; they consist in simple hyperæmia after a short duration of exclusion, in œdematous swelling after a longer duration, in extravasation of blood-corpuscles after a still longer duration, and finally, if the exclusion have lasted a still longer period, in stasis and necrosis. E. KLEIN, M.D.

MEDICINE.

EICHHORST ON THE HEREDITARY TRANSMISSIBILITY OF PROGRESSIVE MUSCULAR ATROPHY.—

Dr. Hermann Eichhorst contributes to the *Berliner Klinische Wochenschrift*, Oct. 20 and 27, a paper on the hereditary transmissibility of progressive muscular atrophy. Hereditary influence has not been as yet, Dr. Eichhorst thinks, sufficiently studied in the etiology of progressive muscular atrophy, though several accurate observers have published some cases in point; but these, in his opinion, ought scarcely to be regarded as true examples of hereditary transmission, inasmuch as they are only instances of brothers and sisters being similarly affected, without any history of their parents having suffered. Dr. Eichhorst communicates in this paper the morbid history of one family in which the hereditableness (*Erblichkeit*) of the disease in question is clearly established. He gives a genealogical table, from which it appears that this disease could be traced by tradition in the first three, and by actual observation in the rest of the members of the family through six generations, directly and collaterally; representatives of three generations are still living, and seven members are personally known to the author. The rule that the male sex are chiefly attacked, is borne out by this family with few exceptions.

In two of the cases the parents have escaped while the children have suffered, and these are, moreover, the only examples of accession before puberty. The disease began similarly in each one, viz., by wasting and enfeebling of the leg and foot, later of the hand and forearm, sometimes accompanied by pain. The affection of the hands occurred earlier in the younger patients.

Dr. Eichhorst thinks that the fact of the lower extremities being attacked first in his cases cannot be explained on the supposition of excessive muscular strain, because the patients were chiefly adult and occupied in hand-labour; but most probably it is the result of the hereditary influence.

He next gives in detail the particulars of the past history and present state of ten cases. The first, being the oldest member of the family examined, and in a high degree typical of the rest, we will give somewhat at length.

Dorothea Braun, aged seventy, was healthy and strong up to her thirty-sixth year, when she was confined to bed during six weeks, and suffered in succession from inflammation of the brain, nervous fever, and diphtheria. After these followed a miscarriage; from this time her legs began to waste, and in a few years her hands also showed signs of weakness; but for some time she could still go about and do a little domestic work. In the meantime she had been delivered of her seventh child (no aggravation of her symptoms occurring from her condition). A shock, occasioned by the sudden death of her husband, produced a rapid development of her symptoms. Pain in her wrists and finger-tips also supervened. At the present time there is considerable wasting of the forearm and hand, chiefly on the extensor surface, so much indeed that there is a deep groove between the radius and ulna; the tendons appear like tight strings. The thenar and hypothenar muscles are withered away; the fingers maintain a position of persistent flexion, any attempt to straighten

them causing severe pain. The thumbs alone are capable of abduction and extension. The skin of the part is cold and bluish. The lower extremities present well-marked talipes equinus: active dorsiflexion of the foot is impossible. The muscles of the lower part of the thigh, leg, and foot are wasted and feeble; the skin is cold and bluish. Respiration and circulation are quiet, the former being entirely costal. The expression of the face is intelligent; the mental faculties are unimpaired; the articulation of words is good, and the muscles of the eyes, face, and tongue are normal. The pharyngeal muscles are well nourished, but deglutition is difficult. The salivary secretion is suppressed. The fundus of the eye is normal. The thorax is flat, but well-formed. The extent of cardiac dulness is normal. The diastolic sound is more distinct than the systolic. The heart's impulse is concealed.

The other patients, descendants of the above, present very nearly the same physical characters, but there are a few points of peculiarity which may be mentioned.

In one, Hermann Braun, aged thirty-six, formerly an infantry soldier, the organs of circulation are seriously disturbed. The heart's impulse is felt in the sixth intercostal space, and extends a finger's breadth on each side of the left mammary line. The cardiac dulness is much more extensive than normal. Over the apex may be heard a systolic murmur following the first sound, and a diastolic murmur displacing the second. Over the centre of the sternum both murmurs are audible, but the systolic is the louder. A loud blowing sound, increased by pressure, may also be heard over the brachial and femoral arteries. Respiration is abdominal. The left pupil is more dilated than the right. This man dates his malady from exposure to cold and damp during his military service.

Another patient, Laura Kiel, aged forty, suffered some time, between the ages of five and sixteen, from chorea and epileptiform attacks. In her nineteenth year she had an apoplectic seizure, followed by loss of power of hands and feet. At the age of twenty-eight she had another apoplectic attack, with right hemiplegia, from which she recovered in three weeks. The catamenia became irregular, and she suffered from 'blood to the head' and vertigo. Since then the muscular atrophy has progressed as in the first case, but more rapidly. At the present she walks in a peculiar manner, lifting her leg high up, then jerking forward the corresponding side of the pelvis, and finally setting down the foot in a stamping, but purposeless fashion.

Ernst Braun, aged eight, one of the two children whose parents escaped the malady, learnt to walk later than usual. He has suffered from hooping-cough, some febrile disorder, followed by dyspnoea, epistaxis, and palpitation. Cardiac dulness increased, extending abnormally in a longitudinal direction. At the heart's apex, a soft murmur follows the second sound. Over the middle of the sternum the first sound is prolonged, and the second displaced by a bruit. There is a louder first sound and presystolic murmur in the second intercostal space. There is no distinct wasting of the muscles of the leg, but the extensors and peronei respond very badly to the induced current. (This is the condition also in the other cases). Talipes varus is distinctly present.

F. B., aged eight, the other child mentioned above, has never been ill before the present time, but like the preceding case, was slow in learning to walk.

There is as yet no perceptible wasting of the leg muscles, but a degree of uncertainty in his walk. There is talipes varus. The legs feel cold, but there is no discoloration of the skin of the part.

The remaining cases need not be specially referred to, the chief interest of the whole paper lying in the fact of all the patients being members of the same family. J. B. BRADBURY, M.D. (Cambridge.)

DISEASES OF CHILDREN.

REISLAND ON CASES OF SO-CALLED CEREBRAL PNEUMONIA IN CHILDREN.—Dr. Reisland relates in *Betz's Memorabilien* (vol. xviii.) three cases of pneumonia with delirium and high temperature ($104^{\circ}3'$ – $105^{\circ}3'$ Fahr.). The children were treated by being wrapped in cloths wrung out of ice-cold water, until the temperature was lowered. Recovery followed in all three cases. SAMUEL GEE, M.D.

FINLAYSON ON THE DANGERS OF DENTITION. Dr. Finlayson (*Obstetrical Journal*, Nov. 1873) analyses the returns of the Registrar-General with regard to the mortality due to teething, and considers that, although they contain some sources of uncertainty, they seem to show in a simple way changes and peculiarities in medical doctrine as to the dangers of dentition. The tables which he has compiled from these returns show, in England, a steady diminution in the mortality ascribed to teething, the maximum being 359 per million for the year 1842, the minimum 188 per million in 1870. The returns for Scotland exhibit a similar tolerably uniform decline, although starting from a much higher level, the maximum being 470 per million in 1857, the minimum 300 per million, reached in 1868; both being greatly in excess of the results given by the English returns—and the average mortality being 386, a proportion never once reached in the latter.

Certain fluctuations in the rate appear to be due to a rise coincident with the outbreak of some epidemic, or an unhealthy season of the year, and may be explained by the supposition that some cases of the prevailing disease were ascribed to the process of teething.

The influence of locality on this item of the general mortality is marked. The tables given by Dr. Finlayson show the proportion of deaths from teething in London and twenty-five other town districts to be more than five times as great as in certain country districts for the four years 1838 to 1841. Bad hygienic conditions being then so potent for mischief to children at the teething period, ought the deadly results to be attributed to the necessary physiological process, in itself alone trifling as a cause of death, or to these and other similar conditions known to be independently disastrous to infant life?

Dr. Finlayson points out the remarkable fact that one half of the deaths ascribed to teething are given as occurring within the first year of life, although the visible phenomena of teething seldom begin before the sixth month; and comparatively few deaths could plausibly be returned from this cause earlier than that age. Hence the process of teething during the remaining months of the year would appear to be more destructive than in the twelve months of the second year, during the whole of which time teething is going on actively. This is all the more remarkable, seeing that deviations from the natural course, and supposed to be perilous, all tend to throw the period later than usual. Is it reasonable to sup-

pose that incisors cause so much more danger than canine or molar teeth? Is it not more probable that the fatal illnesses of infants of early age, being more obscure and difficult to classify, tend to be huddled together into the convenient category of teething?

[There can be no doubt that a vast number of deaths occurring in infancy during the period of dentition are erroneously reported as caused by the teething process, when in reality due to some distinct affection. It is questionable whether any reliable statistics with regard to the actual mortality from teething can be deduced from the Registrar-General's reports, in which the term is so loosely used.—*Rep.*] W. B. CHEADLE, M.D.

SURGERY.

ROSER ON THE MECHANICS OF TRAUMATIC ANEURISM.—Professor Roser, of Marburg, has already pointed out that a series of secondary hæmorrhages depend upon the bursting of small traumatic aneurisms. He regards this as the rule in the arteries of the extremities, and not merely as the result of a single observation. Accurate examination shows that the sac consists of coagulated fibrin connected with the external coat, and not of connective tissue. The sac can in consequence be detached, so that the hole in the vessel itself can be found and then tied. The operation is easy, and can be performed without much assistance. After detaching the aneurism, the wound in the vessel may cause some trouble; in any case the artery must be examined, as two aneurisms of this kind may exist, one higher up than the other.

EDWARD BELLAMY.

BUSCH ON THE USE OF THE ACTUAL CAUTERY IN MYELITIS AND SPASMODIC TORTICOLLIS.—Busch (*Berliner Klinische Wochenschrift*, no. 37, 1873) strongly recommends the use of the actual cautery down each side of the spine and along its entire length in acute progressive myelitis. In spasm of the muscles supplied by the spinal accessory, causing torticollis, he has had excellent results from the application of the cautery along each side of the spine, from the occiput to the first dorsal vertebra.

T. LAUDER BRUNTON, M.D.

TILLAUX ON THE TREATMENT OF NÆVI BY MULTIPLE CAUTERY.—M. Tillaux presented to the Société de Chirurgie (Dec. 10, 1873) an infant whom he had relieved of an erectile tumour of the neck, of the size of a large mandarin orange (on the eighteenth day after birth) by multiple cauterisation with a stilette heated to redness. He introduced the heated stilette on thirty successive days, each day at a point of the circumference towards the centre, the successive cauterisations converging towards the centre. Central suppuration was freely established, and at the same time the tumour underwent complete resolution. There remained only of this large erectile tumour the trace of the cicatrization of the central 'crater' of suppuration.

SYPHILOGRAPHY.

FOURNIER ON DEEP OPHTHALMIA DURING THE SECONDARY PERIOD OF SYPHILIS.—Fournier (*Annales de Dermatologie et de Syphiligraphie*, 1872-3, no. 4) omits from this group iritis and keratitis,

which nevertheless differ more in seat than in anatomical characters from the affections of the deeper structures—choroiditis, retinitis, and inflammation of the optic nerve.

1. *Choroiditis*, most frequent of the deeply seated inflammations, though far less often met with than iritis, is of much greater consequence; if overlooked when recent, and not arrested, it may cause absolute blindness. The clinical signs are—slow progressive amblyopia, fog, *muscæ volitantes*, and dark spots. Fog is most commonly complained of. It is at first slight, then prevents reading and writing, and is often described by the patient to resemble a cobweb constantly floating before the eyes. The web is beset with numerous black spots. An additional sign is feeble definition of objects, their contour being lost, or as if the objects were seen through heated air. Others complain that every object appears covered with lace, or that there is constantly dust in the air. All the signs are more marked when the inflammation is at the posterior pole of the eye.

The ophthalmoscope reveals turbidity and flocculi of the vitreous body, muddiness of the papilla, and occasionally exudation on the choroid. The characteristic sign of the affection is the want of transparency of the posterior media of the eye, which prevents the observer from seeing the condition of the choroid itself. This want of transparency is due, according to Galezowski, not to flocculi in the vitreous humour, but probably to opacity of the posterior part of the hyaline membrane, as this turbidity is observed in patients long before flocculi are present. These come later, as threads of spider's web floating freely and twining in all directions with the movements of the eye. Sometimes they resemble twisted hairs or molecules of dust, filling up the vitreous body. The papilla, seen through this clouded medium, seems hidden by a veil or curtain, as the moon appears when it is seen through a cloud. Some observers consider this condition of the papilla pathognomonic of syphilitic choroiditis. In many cases of choroiditis the turbidity of the vitreous body and the cloudiness of the papilla are all that can be seen. In certain cases of some duration, white spots on the choroid may be detected, scattered in whitish or greyish groups. They denote points of atrophy of the choroid with resorption of the pigment, or of inflammatory exudation. Sometimes little coal-black masses of pigment lie next to or on the edges of these spots. In three cases Fournier states that he, in company with Wecker and Galezowski, saw these whitish spots arranged in horse-shoe groups. Such are the most important and ordinary symptoms of choroiditis; if energetically treated at an early stage, the eye recovers; otherwise it becomes worse and worse, the disorder spreads to other structures, the retina, the iris, and the optic nerve. Its course is insidious; free from pain, affecting the sight slowly, and even spontaneously allowing improvement of vision from time to time; but these improvements are invariably followed by relapses. Galezowski also says that now and then the disease proceeds by attacks of misty vision, almost amounting to amaurosis, alternating with periods where the sight is almost thoroughly regained.

2. *Optic Neuritis*.—Syphilis may attack the optic nerve without affecting any other part of the eyeball. This is rare; commonly the choroid, retina, &c., are implicated. It is usually limited to one eye. The characteristics, are rapidly increasing feebleness of sight; photophobia, especially at the beginning;

bright light in the eyes and coloured vision (photopsia and chromopsia). The ophthalmoscope shows the papilla badly defined; it may be impossible to see where it begins or ends. This is the most striking sign. The papilla is often rather to be guessed at than described. Tortuous vessels are sometimes also present.

3. *Retinitis*, sometimes seen alone, is usually either preceded or followed by choroiditis, iritis, &c. Commonly one eye only is attacked, though it often happens that the other eye is attacked by inflammation of some other structure. It is characterised by marked and increasing weak sight, dread of light, flashing of light, and partial colour-blindness. This increasing want of defining power, so that larger and larger type cannot be read, sometimes shows itself by complete loss of power on certain points of the retina, the patient being able to read one word and not the next, or seeing only half of the word, the other half appearing to be covered with an opaque spot. The constant flashing of light, compared by the sufferers to sparkling balls, fire-works, &c., is a very characteristic symptom of retinitis. The Daltonism shows itself by articles of compound colour having the hue of one of the primitive colours, light green appearing yellow; dark green, blue; violet, red. This Daltonism is, however, not special to syphilitic retinitis, but met with in many alterations of the retina.

The ophthalmoscope shows exudations and extravasations of blood (apoplexy) on the retina.

The exudations, which are the pathognomonic sign, are of two kinds; one being serous effusions or infiltrations, the other solid opaque exudations. The former, being transparent, allow the vessels to be seen as through a gauze curtain, which most frequently occupies the fundus and surrounds the papilla. The solid spots are white, without defined edge; sometimes large, sometimes small, scattered over the surface or ranged along the course of the vessels. Very often they form on the macula, and so completely destroy central vision. Less often than the preceding conditions, hæmorrhagic spots are observed on the retina; there is nothing special respecting them, and they are caused by rupture of veins. The progress of retinitis is always slow. The disease has stationary intervals, with stages of increase. Retinitis is the most curable of all the deep affections of the eye. Yet the prognosis depends greatly on the part of the retina attacked, the affections of the fundus being by far the most important.

These three forms are those met with in syphilis; but though separately described, they rarely occur singly in one patient. A strong characteristic of their syphilitic origin is their developing one after the other, or simultaneously, in different or even in the same eyes. In the majority of cases, the deeper affections are sequæ or companions of iritis. Again, when originating in the choroid, the disease, if not checked by energetic treatment, spreads to the retina and optic nerve, producing in course of years complete blindness from destruction of the retina or nerve, characterised by copious pigmentary deposit on the retina.

Having pointed out the difficulty in many cases of determining in a given case of inflammation of the deeper structures, whether it be due to syphilitic or to other cause, without reference to the patient's history or condition elsewhere, Fournier recapitulates the characters which are usually present in syphilitic disease. They are:—

1. Multiplicity and complexity of the lesions produced;
2. The localisation of the disease near the posterior pole of the eye;
3. The circular arrangement of the exuded matter;
4. The peculiar and rapid change in the transparency of the vitreous body and the misty condition of the bottom of the eye.

Nevertheless, however marked these groups of symptoms, they are not pathognomonic, and should be supported when making a diagnosis by reference to the antecedent and general condition of the patient. Unfortunately, however, these cases of syphilitic ophthalmia do not appear only in patients whose other symptoms have been severe; on the contrary, the patient's previous history in many cases shows a light course of the disease. In treatment, the extreme danger to the sight demands most active medication. Mercury, in its most energetic and soluble forms, and even in large doses, should at once be given; and mercuric inunctions should be, in Fournier's opinion—on account of its being the most certain way of bringing the system under mercuric influence—the invariable mode of treatment, without delay, and must be continued for a considerable period.

BERKELEY HILL.

MISCELLANY.

THE MICROSCOPICAL SOCIETY OF VICTORIA, which, at this early stage of its existence, has a good member-roll, has held its first general meeting at Melbourne, the president (Mr. W. H. Archer) being in the chair. A rich and varied collection of microscopes and objects was shown by members of the society, and during the evening these exhibits were examined with interest. The president, in delivering his inaugural address, explained that the society would consist of two classes of persons—viz., skilled workers, who were called members, and students and amateurs, who were called associates. Mr. Archer went on to say that in Victoria there were microscopists who were possessors of good instruments, and who knew thoroughly how to use them. The establishment of this society, it was hoped, would induce most of these gentlemen to co-operate, sooner or later, with one another, for though at intervals certain very valuable special professional work had been accomplished in Melbourne and elsewhere, yet so far as published results were concerned, not only Victoria, but Australia generally, was, microscopically speaking, almost altogether an unknown land. The address was followed by some interesting statements and demonstrations, and altogether the inaugural meeting was a very successful one. The holding of ordinary meetings has commenced, and the society appears to have a useful career before it.

THE DANGER OF WET COAL.—People who prefer wetting the winter's store of coal to the dust on putting it in their cellars do not, we believe, generally know that they are laying up for themselves a store of sore throats and other evils consequent upon the practice. But so it is said to be. Even the fire damp which escapes from coal mines arises from the slow decomposition of coal at temperatures but little above that of the atmosphere, but under augmented pressure. By wetting a mass of freshly broken coal and putting it into a warm cellar, the mass is heated to such a degree that carburetted and sulphuretted hydrogen are given off for long periods of time, and pervade the whole house. The liability of wet coal to mischievous results under such circumstances, may be appreciated from the circumstance

that there are several instances on record of the spontaneous combustion of wet coal when stowed into the bunkers or holds of vessels. And from this cause, doubtless, many missing coal-vessels have perished.

THE AMAZON TRIBES.—The Peruvian Amazon Exploring Commission lately issued a report, from which we find that malarious fever is prevalent on both banks of the mighty river, causing a large mortality among the native population. Adults and children are given up to the filthy habit of geophagy, or dirt-eating, a practice productive of innumerable physical evils. It is common to find on the Amazon children of three years of age smoking, and 'not averse to rum.' Altogether, the natives appear to be sunk in an abyss of moral filth and depravity from which nothing but a strong tide of European immigration can lift them.

FREAK OF NATURE.—Dr. W. H. Bent, of Argyle, N.S., reports the following peculiar case of monstrosity occurring in a child whose parents reside in Pubnico. It has three legs in perfect use, two complete sets of sexual organs (male). Two perfect arms, and two imperfect ones—the latter growing from the middle of the back and curving in a line with the lower ribs. The head is finely developed, and what appears to be a second one is situated half way down the left side of the neck. It is considered a great wonder among the French Acadians.

FUCHSIN AS AN ANTISEPTIC.—This anilin preparation is said by Launois, in the *Comptes Rendus*, to be a remarkably powerful antiseptic. One per cent. added to a solution of gelatine, not only preserved it, but a piece of fresh meat wrapped in paper soaked in this medicated gelatine solution kept for months without a sign of putrefaction. One forty thousandth part ($\frac{1}{40,000}$) added to urine, prevents it perfectly from decomposing. Such experiments merit careful repetition.

DUGONG BACON is said to have become an article of sale at Maryborough, and is described as being, when properly cured, a relishing article of diet, more especially for the breakfast table. It is said to have the flavour of good bacon with just an agreeable 'bloater' twang added.

TWENTY dollars a day is the amount of fine incurred by the law of Nova Scotia, coming in force on May 1, for practising medicine without being registered.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, JANUARY 14, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

THE MICROSCOPIC CHARACTERS OF ATMOSPHERIC DUST.*

This investigation was undertaken in order to ascertain whether any connection could be established between the microscopical characters of the organised particles found in atmospheric dust, and the prevalence of epidemic diseases. The observations were made in Calcutta and the neighbourhood.

The author employed for the purpose of collecting the formed particles contained in the air the instrument first devised by M. Pouchet, to which he gave the name 'aeroscope.' This instrument, which has been modified by various observers, particularly by Dr. Maddox (see his paper on the subject in the *Monthly Microscopical Journal* for 1871), has been further improved by Dr. Cunningham. As now used it consists of a large vane, to the axis of which a funnel is fixed horizontally in such a way that its mouth faces the wind. The tube of the funnel is drawn out to a capillary orifice, opposite to which an ordinary cover-glass can be so placed that the current of air as it issues from the orifice is directed against it. After a few hours, or days, the exposed surface of the glass becomes covered with a more or less circular layer of dust, which can be examined microscopically with great ease after the addition of water or other suitable liquid to the deposit. This apparatus was set up at Calcutta and in the suburb of Alipore, in the open air. It was also used to examine air derived from the Calcutta sewers. The method of recording the results was to figure every object of organic form that presented itself in the dust disk. The results were as follows.

1. That bacteria 'can hardly ever be detected among the constituents of atmospheric dust,' but 'are frequently to be found amongst the particles deposited from the moist air of sewers.'
2. That 'the addition of dry dust which has been exposed to tropical heat, to putrescible fluids, is followed by a rapid development of fungi and bacteria, although recognisable specimens of the latter are very rarely to be found in it while dry.'
3. 'That spores and other vegetable cells are constantly present in atmospheric dust, and usually occur in considerable numbers. The majority of them are living and capable of growth and development.'
4. That no connection can be traced between the number of organisms present in the air, or the presence of any special form of organism and the prevalence of any epidemic disease.
5. That the amount of inorganic and amorphous particles

suspended in the air is dependent on the moisture of the atmosphere and the velocity of the wind, but that these conditions do not influence the number of organised particles.

The research is important, as affording evidence more decided and more positive than any which has yet been published, (1), that atmospheric dust consists largely of organic forms (in contradiction to the assertions of the French heterogenists), and (2) that these forms are almost entirely those of spores of fungi. The most important results bearing on pathology are first, the additional proof given that bacterial matter can be carried in the air in such a state as to determine the contamination of liquids capable of supporting bacterial life, even when the air is much drier than it ever is in Europe; and secondly, the confirmation which it affords of previous observations, that bacteria exist in atmospheric dust so sparingly that in general they cannot be detected.

J. BURDON SANDERSON, M.D.

CREMATION.*

There exist five ways of disposing of a departed brother; firstly, by eating him; secondly, by deputing that office to the beasts of the field or the fowls of the air; thirdly, by embalming and mummifying him after the method of the ancient Egyptians, or by petrifying him into a stony material, capable of being cut up into slabs, as was recently seen in the remarkable table exhibited by a Florentine professor; fourthly, by burying him in the ground, and trusting, somewhat rashly, the disinfecting power of Mother Earth, as is the practice in these degenerate days; fifthly, by cremation, or the destruction of the soft parts of the body and the calcination of the bones by fire.

Other methods of abolition exist; for instance, the committal of the body to the deep, the use of quicklime, and the employment of caustic potash. The two former may be dismissed as only susceptible of occasional or local application, and the latter as involving the reduction of the human form divine to a soapy consistency—an unwholesome and repulsive idea.

Of the five principal systems, the first is inapplicable to the fastidious tastes of a civilised people. The second is barbarous and wasteful. The third is alike unpractical, wasteful, and expensive. Thus the whole question resolves itself into the consideration of the rival methods of inhumation and cremation.

Inhumation possesses, among Christian nations, the advantage of prescription. A certain halo of sanctity surrounds the churchyard, and a sickly sentimentality induces nations to persevere in a practice at once irrational and unhealthy. Among the ancients, during many periods, cremation was the prerogative of the noble, and among the Hebrews was a privilege reserved for the mighty and honourable dead. The bodies of the vulgar appear to have been buried anywhere, but those of the great were almost invariably burnt—the calcined bones being collected, placed in an urn, and preserved with due reverence. The affection of Christian nations for inhumation can only be explained by its divergence from the pagan ceremony of cremation, inasmuch as, viewed chemically and economically, the adoption of interment, far from being an advance in civilisation,

* On Microscopic Examinations of Air. By D. DOUGLAS CUNNINGHAM, M.B. (Appendix to the Ninth Report of the Sanitary Commissioner with the Government of India, 1872.)

cannot fail to be regarded as a decided retrogression—substituting, as it does, the tardy and uncertain action of nature for the rapid and positive methods prescribed by science. The law of nature is—change; and the mortal envelope of man is no sooner bereft of the soul than, if left to itself, it immediately undergoes the operation of those physical laws which reduce its constituent elements into more simple combinations—that is to say—to water, to gases (among which carbonic acid gas, carburetted hydrogen, and ammonia, largely predominate), and to mineral salts (lime, magnesia, potash, soda, and oxide of iron). By the combination of these various bases with phosphoric and carbonic acid are formed certain special and well-known salts (carbonates and phosphates of lime, magnesia, &c.) As a general rule, it may be assumed that the human body contains seventy-five parts of water to twenty-five parts of solid matter. The gases are assimilated by the vegetable world through the agency of the leaves of plants; while the salts, combining with the earth, contribute to nourish their roots. Thus, in obedience to the law which pronounces matter indestructible, the mortal part of man gives back to the earth the phosphates, carbonates, and other fertilising solids drawn originally from the storehouse of nature. Man, beasts, and plants die and decompose, not only that they may give place to other organisms, but that their remains may serve as pasture for succeeding generations. Embalming and petrification, besides being costly and troublesome processes, labour under the disadvantage of crowding the earth with inactive matter, and are far more opposed to natural laws than the prevalent system of inhumation, under which man literally pays the debt of nature by giving back to Mother Earth all that he has taken from her. Mummification of all kinds is also attacked on the ground that, if the Egyptian method prevailed over the whole surface of the earth for about three thousand years, the dead would displace the living, and the whole world be covered with a stratum of mummies. Inhumation, then, is a far more philosophical system than embalming and petrification, inasmuch as it permits the unimpeded operation of the laws of nature.

Unfortunately, however, inhumation is attended with certain serious inconveniences. Graveyards and cemeteries, crowded with decomposing masses of humanity, exercise a prejudicial influence on the health of the living who have been foolish enough to allow themselves to be inconvenienced by the dead. Suggestions have been made that cemeteries should no longer be considered perpetual, but should be closed at the end of a certain time, and ten years after the last funeral should be yielded back to agriculture. It is difficult to believe that a system of moveable cemeteries would, in the present state of human knowledge, obtain the sanction of the popular voice. The consumption of vegetables whose roots had been nourished by the defunct members of a family would hardly be enjoyed by the survivors, unless, indeed, they possessed the philosophic mind and robust appetite of the French gentleman who declared that, with a certain sauce, *on mangerait bien son père*.

Two of the principal drawbacks to inhumation are the infection of the air and the contamination of water. All precautions to the contrary notwithstanding, a mass of decomposing organic matter cannot fail to fill the air with unwholesome and mephitic vapours which, although charged with

matter valuable to the vegetable world, exercise a deleterious influence on mankind.

Still more destructive is the infiltration of water highly charged with organic matter into wells, springs, and streams used for drinking purposes. Contagion and death have many a time and oft been shown to be due to the infiltration of graveyard water. Dr. Prosper de Pietra Santa, who has devoted much research to this important subject, cites the example of the hamlets of Rotondella and Bollita. The cemeteries of these unfortunate villages were situated on the summit of wooded hills (at the distance duly prescribed by law), and to all outward appearance were installed under exceptionally favourable conditions. Unfortunately, the springs destined to the daily use of the inhabitants emerged from the base of the hills surmounted by the cemeteries; and as these springs were the product of the rain-water, which, falling on the surface of the cemeteries had filtered through the ground, and had become impregnated with the organic matter encountered during this process, a time at length arrived when the drinking water of these two villages became sufficiently contaminated to produce a frightful epidemic.

For several years past the doctors of Italy have been arriving at the conviction that the only escape from the inconvenience and unhealthiness of inhumation is to be found in a recurrence to cremation. Drs. Polli, Gorini, Brunetti, and Pini have devoted great attention to the practical details of the operation, and the result of their experiments cannot fail to interest sanitary reformers in this and other countries. Dr. G. Pini assisted at a cremation at Florence. This was no mere experiment, but the funereal rite of an Indian prince, the Rajah of Kellapore. On the banks of the Arno were enacted the ceremonies nightly performed on the banks of the sacred streams of India, the Ganges, the Krishna, or the Tummā. At the hour of midnight, the mortal remains of the Indian prince were carried to the banks of the river. The funereal pile consisted of a heap of wood, about five feet square, firmly fixed and secured to the ground by seven bars of iron. A second heap of wood was thrown loosely around. After certain religious ceremonies, the pile was powdered with camphor and other aromatic substances, and the dead rajah was laid upon it. The body was anointed with pure naphtha, the features covered by a mask of some greasy substance, and all the limbs covered with resinous matter, betel leaves, perfumes, and powdered sandal-wood. The corpse was then covered with more layers of wood, alternated with inflammable substances, and the next of kin to the prince set fire to the pile. Although the flame was fanned by a strong wind, the body was barely consumed at seven o'clock the next morning. At ten, when the fire had almost entirely burned out, nothing remained but a heap of ashes. An Indian priest collected a small quantity from the centre of the heap. The remainder was thrown to the wind, in the direction of the current of the Arno.

Although this operation was, on the banks of the Arno, attended with the success constantly witnessed in India, it must be admitted that it proved not only tedious but expensive. Ten hours consumed in the destruction of a human body must appear to Western nations an enormous space of time, and the cost of precious woods, resins, and oleaginous substances, would in itself act as an efficient bar to the general adoption of the Indian method.

It cannot be denied that cremation is an operation of considerable difficulty when attempted in the open air. The experience of Byron and Trelawny in burning the body of Shelley is a case in point. Mr. Trelawny 'got a furnace made at Leghorn, of iron bars and strong sheet iron, supported on a stand, and laid in a stock of fuel and such things as were said to be used by Shelley's much-loved Hellenes on their funeral pyres.' The bodies of Shelley and Williams had been for some time in the water, had been buried in the sea-sand, and were, when exhumed, in an advanced state of decomposition. The body of Williams was first disinterred, and presented a hideous spectacle. 'The funeral pyre was now ready; I applied the fire, and the materials being dry and resinous, the pinewood burnt furiously, and drove us back. It was hot enough before, there was no breath of air, and the loose sand scorched our feet. As soon as the flames became clear, and allowed us to approach, we threw frankincense and salt into the furnace, and poured a flask of wine and oil over the body. The Greek oration was omitted, for we had lost our Hellenic bard. At four o'clock the funeral pyre burnt low, and when we uncovered the furnace, nothing remained in it but dark-coloured ashes with fragments of the larger bones. Poles were now put under the red-hot furnace, and it was gradually cooled in the sea. I gathered together the human ashes, and placed them in a small oak box, bearing an inscription on a brass plate, screwed it down, and placed it in Byron's carriage.' This operation may be designated fairly successful, but the burning of the body of Shelley was attended with peculiar circumstances. 'I had taken the precaution,' continues Mr. Trelawny, 'of having more and larger pieces of timber, in consequence of my experience of the day before of the difficulty of consuming a corpse in the open air with our apparatus. After the fire was well kindled, we repeated the ceremony of the previous day, and more wine was poured over Shelley's dead body than he had consumed during his life. This, with the oil and salt, made the yellow flames glisten and quiver. The heat from the sun and fire was so intense that the atmosphere was tremulous and wavy. The corpse fell open, and the heart was laid bare. The frontal bone of the skull, where it had been struck with the mattock, fell off; and, as the back of the head rested on the red-hot bottom bars of the furnace, the brains literally seethed, bubbled and boiled, as in a cauldron, for a very long time. The fire was so fierce as to produce a white heat on the iron, and to reduce its contents to grey ashes. The only portions that were not consumed were some fragments of bones, the jaw, and the skull, but what surprised us all was that the heart remained entire. In snatching this relic from the fiery furnace my hand was severely burnt, and had any one seen me do the act, I should have been put into quarantine. After cooling the iron machine in the sea, I collected the human ashes and placed them in a box, which I took on board the *Bolivar*.'

It is not our purpose to discourse on the taste displayed by the author of this highly sensational description, but the technical details demand some attention. Aware from the first of the difficulty of burning a corpse, Mr. Trelawny provided himself with a furnace, which seems to have done its work very well when aided by a large quantity of excessively dry and resinous fuel. Oil appears also to have been freely used, but even with all these ap-

pliances the operation lasted for a considerable time. From the ghastly experiment on the body of Shelley and the tedious and costly process successfully employed in the case of the Rajah of Kellapore, it appears evident that the ancient method of cremation by means of a funeral pile is tiresome, expensive, and subject to occasional failure. It remains, then, to examine those methods which call into requisition the resources of modern science for the purpose of insuring perfect incineration of the tissues and thorough calcination of the bones within a reasonable time, and at such moderate cost as may render their general adoption practicable.

At the Milan gasworks, Dr. Polli made a notable experiment. In a cylindrical retort of refracting clay used for the distillation of coal-gas, was placed the body of an unfortunate poodle dog, drowned for contravention of the muzzle laws promulgated by the police. The dog weighed twenty-two and a half pounds. The apparatus was heated by a crown of flames issuing from a perforated circular tube. In order to render combustion as active as possible, the coal-gas was mixed with a certain quantity of pure air. Our readers will recollect that this addition of atmospheric air is the principle of the Bunsen burner, which ensures perfect combustion of coal-gas, and produces a maximum of heat with a minimum of light. The cremation lasted several hours, producing a thick smoke, with an odour of roast meat. After carbonisation, the skilful chemist succeeded in obtaining complete incineration, that is to say, the calcination, of all the solid parts of the body, which weighed one pound fourteen and a half ounces.

Satisfied with the result of this experiment, which proved the possibility of reducing the carcass of an animal to ashes by ordinary coal-gas, Dr. Polli proceeded with a second and more complete experiment. One improvement was the disposition of a vertical retort in such manner as to consume the gaseous products of combustion. This is easily effected by placing at the upper orifice of the retort a second ring of gas jets. On this occasion, better arrangements were made for carrying out the principle of the Bunsen burner, with the result of producing the complete incineration of a dog weighing forty-two and three-quarter pounds in the space of a couple of hours. On this occasion the solid residue weighed only two pounds three ounces. Dr. Caffè mentions the idea of an engineer, M. Rudler, who suggests the utilisation of the gaseous products. Burnt in a retort by coal-gas, the body consumed may be made itself to yield illuminating gas, a process which possesses, at least, the merit of economy.

Professor P. Gorini, the author of an important work, '*I Vulcani Sperimentali*,' made some interesting experiments in his laboratory at Lodi during the month of September last. These were witnessed by a brilliant meeting of scientific men. The process of Dr. Gorini differs materially from those practised by other professors of the art of cremation. A substance, the composition of which is still a secret, but which we are probably not far wrong in supposing to have been a mixture of caustic soda with nitre, or with chlorate of potash, was melted in a crucible at a very high temperature. On the liquid attaining the proper degree of ebullition, portions of a human body, legs, arms, &c., were thrown into it. The moment the limb touched the incandescent liquid, it was enveloped in flames, and in the space of twenty minutes was completely destroyed, the volatile part

disappearing in the form of gas, while the fixed solids, calcined and incinerated, remained at the bottom of the crucible on a metal grating. The receptacles or crucibles are made of earthenware, and the furnace, built of simple bricks built up without cement, is heated by coke. This experiment was completely successful, the work of destruction being accomplished without any disagreeable crackling sound or unpleasant odour. The gas was allowed to escape to nourish the vegetable world, and the ashes were committed to the earth to replace the metallic bases previously contributed to the formation of a human body.

Few have given more time and study to practical cremation than Professor Brunetti. This gentleman sent a case of apparatus to the Vienna Exhibition, and records his conviction—arrived at after five experiments upon human bodies—that the total incineration of a corpse and the complete calcination of the bones by fire is, under ordinary conditions, impossible. He has tried various combustibles, gas retorts, closed vessels, and the open air, and has arrived at the conclusion that special apparatus is indispensable to the success of any attempt at perfect cremation. His apparatus consists of an oblong furnace built of ordinary, or, still better, of refracting brick, and furnished with ten side openings, in order to give the power of regulating at will the draught, and consequently the intensity of the fire. In the upper part is a cornice of tiles, destined to support an iron framework, above which is the dome-shaped roof, furnished with cast-iron shadows, which may be opened or closed by means of regulators, to shut in the flame and concentrate the heat. The body to be incinerated is placed upon a thin metallic plate, suspended by stout iron wire. The operation may be divided into three sections; firstly, the kindling of the body; secondly, its combustion; thirdly, the incineration of the soft parts and the calcination of the bones. Wood having been piled up in the furnace and lighted, the body catches fire at the end of half an hour. A considerable quantity of gas is now evolved, and the movable shutters come into operation. The body then burns freely; and if the pile of wood have been deftly arranged, complete carbonisation ensues at the end of a couple of hours. The shutters are then opened, another sheet of metal is lowered over the carbonised mass, to concentrate the heat still more, and the wood is renewed. By means of this apparatus, and at the cost of 160 or 180 pounds of wood, complete cremation is achieved in two hours more. When the furnace is cold, the residue is collected and placed in a funeral urn. The last experiment of Dr. Brunetti was made upon the body of a man who died, at the age of fifty, of chronic bronchitis. The weight of the body was 114½ pounds, and was reduced by cremation to a fraction under four pounds. It has been suggested that, when extreme solicitude is felt as to the identity of the ashes, the body might be wrapped in an asbestos winding-sheet.

These experiments were suggested at the Medical International Congress, held at Florence in 1869, by Professors Coletti and Castiglioni; and the opinion of these authorities was supported by a resolution of the Congress expressing a wish that 'every possible means should be employed to obtain legally, in the interest of the laws of hygiene, that the incineration of bodies should be substituted for the present system of inhumation.' A similar vote was passed at the Congress held at Rome in 1871, and recently

the Royal Institute of Science and Letters of Lombardy has offered the quinquennial (1877) Secco-Commeno prize to the advocates of cremation in the following terms.—'Indicate a method of cremation of dead bodies, such as may be substituted for the present method of inhumation, in order to prepare the way for this hygienic reform. The object is to demonstrate by arguments, supported by experiments upon animals, that the method is free from inconvenience, that it is expeditious and economical, and of a nature to respect civil usages and customs and the proprieties of social life.'

It is—to say the least—remarkable that the experiments practised in Italy should have been overlooked in this country, where sanitary laws and sanitary questions attract, very properly, a large share of public attention. An absolutely perfect method of cremation fulfilling all the conditions laid down by the Royal Institute of Lombardy, has perhaps, yet to be discovered, but it is remarkable that successful experiments have already been performed with so poor a fuel as wood. Of the three modern methods described, the process of Dr. Gorini is incomparably the most rapid. An operation requiring only twenty minutes throws completely into the shade the furnace of Dr. Brunetti—otherwise an entire success—and the retort advocated by Dr. Polli. The only objection to Gorini's method is its expense. At present the combustion of a single body costs nearly 3*l*., a sum far too high to admit of its general adoption; but it is affirmed that this expense is only incurred on account of the necessity of employing a large quantity of fuel to fuse the material employed in the actual cremation. This high temperature once attained, the incandescent material will serve for the destruction of many bodies. The expense, therefore, will diminish in proportion to the number of 'subjects.' For instance, if a dozen were operated on at the same time, the cost of each cremation would be reduced to five or ten shillings.

This is really the most important consideration of all. The ancient pyre, under favourable conditions, does its work well, but slowly, and labours under the disadvantage of costliness. The retort system of Dr. Polli occupies, in common with the ancient method, a considerable space of time, and a similar objection applies to the Brunetti process. This latter system possesses the merit of economy in fuel, but should Gorini's prove, in practice, equally inexpensive, its tremendous rapidity would give it precedence over every method yet discovered.

At the first glance, it is difficult to see what objection could be raised by a practical people against cremation, either on the score of public decency or of proper veneration for the dead. By cremation the rapid action of fire is substituted for the slow, but precisely similar, process of decomposition. Once adopted, the proceeding would appear natural enough. The funeral procession would halt at the chapel of the cemetery. After the solemn and touching funeral service had been performed, the corpse would be lowered into a vault, and subjected, *non coram populo*, to the Gorini process, or some other more perfect method yet to be invented. A short space of time might be profitably spent in prayer or meditation. At the conclusion of this period, the ashes of the dead would be rendered back to his family, in an appropriate urn, which might be placed in a vault or in such other receptacle as might be deemed more

fitting, or the ashes themselves might be committed to the earth. No rational sentiment of love or veneration would thus be violated, and the ceremony, while losing nothing in dignity and solemnity, would be deprived of much unnecessary repulsiveness. Another, but by no means unimportant consideration is, that the dread of premature interment—a terror acutely felt in hot countries where almost immediate inhumation is rendered necessary by the climate—would be effectually disposed of. Nevertheless, numerous objections have been raised. It has been urged that the complete destruction of a corpse would at once hold out a premium to poisoners by destroying all possibility of detection; but this consideration is hardly of sufficient weight to induce the destruction of innumerable lives, by pestiferous air and contaminated water, to secure the detection of a few criminals. Sentimental objections have already been dealt with, but it is singular to find that the proposed introduction of cremation has raised a storm among archaeologists, who, ignoring the printing press, have imagined that without the records of the tombs, the present age, its acts and deeds, might pass away from the ken of posterity as completely as the ancient civilisations of Central America and Malacca. Objections of this kind can only provoke a smile, as, even if dire oblivion should be the ultimate doom of the nineteenth century, the opinion of the world 2,000 years hence is of little moment when compared with the health of those now inhabiting it. In the words of the learned rector of the University of Padua, Professor Coletti, 'Man should disappear, and not rot; he should no more be transformed into a mass of corruption—the source of filthy and injurious exhalations—than into a grotesque mummy—a shapeless mixture of pitch, resin, and perfumes. Man should become a handful of ashes, and nothing more.'

Although very thoroughly impressed by the opinion of the learned Paduan, we cannot shut our eyes to the obvious truth that the advocates of cremation have before them a long and difficult task. Man is unfortunately more frequently governed by prejudice than by reason. We are, therefore, quite prepared to hear cremation denounced as disgusting, heathenish, abominable, Popish, brutish, and atheistic. Nevertheless, the time has come when some effort must be made to abolish the evils inseparable from inhumation in thickly inhabited countries, where the health of the living is often seriously affected by crude and unscientific methods of disposing of the dead. Vast improvements have been made in the art of preserving life, and it is surely a small thing to ask that science should prescribe an unobjectionable method of dealing with the material remains of dead humanity. The invention, publication, and ample discussion of improved methods of cremation can hardly fail to prepare—in time—the public for the adoption of a system against which can be urged few objections beyond those of a purely sentimental nature.

CLINICAL LECTURE ON THE TREATMENT OF DISEASES OF THE HEART, AND THE HYGIENE PROPER FOR THEM. DELIVERED AT THE HÔPITAL ST.-ANTOINE, PARIS. BY DR. PÉTER.

In the presence of organic disease of the heart in the adult, it is useless to cherish delusions by hoping for cure. The disease is incurable; and the only

thing to be hoped for, which is much, is to retard the evolution of the disease, to combat the but too near advent of asthenia of the vessels and heart, the production of visceral lesions, and, indeed, the whole series of subordinated symptoms.

Palpitations appear at the commencement of the cardiac disturbances, and are characteristic of the first phase of heart-disease. They are not only to be dreaded as functional disturbances, but because they constitute the primary cause of hypertrophy of the heart. Digitalis is most commonly used as a resource against them, and numerous theories and experiments respecting the way in which this substance acts have been accumulated; the only thing thoroughly ascertained about it being that, in moderate doses, it calms palpitation of the heart. It is, however, a remarkable fact that it exercises this influence over palpitation where there is cardiac lesion, whilst it scarcely seems to possess any power over nervous palpitation. M. Péter prefers digitaline, because it is easier to use, and does not produce sickness. He prescribes a granule containing one milligramme to be taken every morning; and if that be not sufficient, he increases the dose to two, one in the morning and one in the evening, scarcely ever going on to four or five. For nervous subjects he adds ether, cherry-laurel water, or chloral; the ether in the very convenient form of pearls (from two to four or six during the day), the cherry-laurel water (*aqua laurocerasi*) in the simple form of five to ten drops on a bit of sugar twice or thrice a day; and finally the chloral, if sleep be defective, in doses of from two to three pearls in the course of the evening.

Pain is another indication for therapeutic treatment; it is situated above the nipple in the upper sternal region, and is either spontaneous or brought on by pressure. It would be attributable to the spreading of the lesion to the cardiac plexus, or to the existence of a cardio-aortic lesion. It is not only painful, but constitutes a menace of sudden death. The pains are accompanied by great anxiety. If the suffering be acute, we must not hesitate in applying half a dozen scarifying cupping-glasses or leeches over the submammary region; if the danger be less pressing, blisters will suffice. Apply one of the size of the palm of the hand to this region; when it is dried up, put four or five little ones over the præcordial region. From 4 to 6 or 8 grammes (1 to 2 drachms) of bromide of potassium should be taken every day for some time. It produces a remarkable sedative effect on cardiac disturbance and the concomitant dyspnoea. It is even of advantage to continue the use of bromide of potassium from eight to ten days, gradually diminishing the dose, which should never fall below one gramme. At the moment when the access is most marked, administer from two to four or six ether pearls at intervals of an hour, or the official preparation in drops on a piece of sugar. If the attacks of pain or dyspnoea reappear at short intervals, we must apply the actual cautery to the submammary region, in the second or third intercostal space near the sternum. If the pain be not intense, or if the patient be a woman, a Milan fly should be applied once a week, and at the same time the region of the heart should be painted with tincture of iodine night and morning for three successive days.

In a second period, called by M. Péter the chemical period, hæmostatic troubles result from the stasis of the blood in the lungs, and the excess of tension in

the pulmonary arteries, whence dyspnœa and anæmia supervene. In order to relieve the congestion of the pulmonary arteries, it is useful to excite their secretory machinery; and for this purpose M. Péter prescribes kermes mineral and ipecacuanha. The kermes should be given in doses of 5 centigrammes ('075 grain) in the course of a morning, in the form of a lozenge, for instance, of which eight contain nearly 5 centigrammes of kermes; the patient sucks them in the course of a morning. He gives ipecacuanha in the same form; six pastilles, containing 10 centigrammes of powder, in the course of a morning, in order to obtain a purely expectorant effect; or in the space of an hour, if it be desired to bring on nausea, which is a good means of relieving the congestion, since by contracting the size of the vessels it accelerates the circulation. He advises that these agents should only be used once in the week or fortnight, this being a general basis for treatment, the indications for which are specially drawn from the degree of dyspnœa existing. He, however, recommends the daily use of balsamic preparations, especially balsam of tolu, which keeps up a salutary secretory hyperæmia on the surface of the respiratory mucous membrane. The tolu is given in the form of syrup, 50 or 60 grammes daily, and lozenges, of which the patient takes twenty in the course of the day. The tolu balsam may also be associated with Canada balsam in a conjunction of equal parts of syrup of tolu and Canada balsams. When there are bronchial râles, a drink composed of infusion of pine-shoots sweetened with syrup of tolu should be ordered. When there is bronchial congestion, Morton's balsamic pills are also an excellent medicine, given in doses of one or two every two or three days. We must not despise as an adjuvant, the making the patient inhale ordinary aromatic salts frequently during the day; these inhalations not only act on the nervous system, they likewise stimulate strong inspirations which, on the one hand, help by mechanical means in removing the congestion of the vesicles by forcibly relaxing them, whence ensues the flowing back of the blood which circulates in their walls; whilst, on the other hand, the inspirations are directly beneficial to the hæmatosis by causing strong columns of air to penetrate the lungs. For the same reason, compressed air-baths may be useful. For the prevention of these congestions it may be useful to have irritant frictions made with Fioraventi's balsam on the anterior part of the thorax. But when the patients are suddenly attacked with symptoms of suffocating catarrh of diffused capillary bronchitis, there must be no hesitation in opening the passages freely, in using scarifying cupping-glasses, in administering an emetic at proper intervals.

For the anæmic condition, preparations of iron are indicated, but most specially hydrotherapeutics. M. Péter prefers the application of simple or modified lotions to his patients to the use of the douche, which gives too great a shock. Hydrotherapeutic treatment is besides the best preventive of those pulmonary accidents which give rise to more or less formidable pulmonary congestions. In the third stage, or period when we meet with multiplied visceral congestions, the medication should be of a very varied character, the capital indication being always to remove the congestion of the lungs and liver.

For this purpose drastics and diuretics are indicated, but must be used with caution. For instance, enormous doses of German brandy are commonly

administered when 5 grammes would be sufficient; and if this dose be too weak, it can be doubled with advantageous effect, and without any risk to the patient. M. Péter often orders the following electroly prescribed by Cruveilhier.

| | |
|--------------------------|------------------|
| Powdered senna . . . | 4 grammes. |
| " scammony . . . | 1 gramme. |
| " gamboge . . . | 30 centigrammes. |
| " jalap . . . | 4 grammes. |
| Syrup of buckthorn . . . | 30 grammes. |
| Honey . . . | 30 grammes. |

A teaspoonful of this mixture should be given in the morning, the dose being increased to two or three if necessary. Plethoric patients should be bled, but very slightly; and the operation should not be repeated, even if the patients request it. Local blood-letting is often indicated. When the patient is too anæmic to be bled, blisters may be of great use.

With regard to the digitalis, which is given in such a matter-of-course way, it should only be prescribed when there are insupportable palpitations, and then only for a few days in that asthenic period, so as not to diminish the contractile power of the heart. It must not be used when the contractions are feeble, when there is cyanosis, intense visceral congestions or drowsiness. The heart and the great vessels must then rather be stimulated by the help of frictions on the skin made with alcoholic tinctures; quinine, the aromatic alcoholates of cinnamon or peppermint, wine, brandy, ether, acetate of ammonia, and above all coffee, may be administered internally. At its outset, dyspnœa is connected with palpitations, and is calmed by digitalis and acetic and sulphuric ether; later on, it is the result of pulmonary congestion, a complication for the relief of which we have indicated the necessary measures. Finally, in the third period, dyspnœa results from cardio-vascular asthenia, with pulmonary cedema. In this contingency, bromide of potassium in from two to five gramme doses gives wonderful results.

As to the occasionally persistent and distressing sleeplessness, it must on no account be combatted by opiates, which completely destroy the already small appetite; we must here also administer the bromide of potassium in rather large doses of from two to six grammes, or chloral, which sometimes succeeds better. We may also combine these two drugs, giving two grammes of the first in proportion to one of the second. These drugs are also strongly called for in the case of nocturnal disturbance, accompanied by dyspnœa and the sensation of strangulation. In the fourth period, characterised by multiplied dropsical attacks, we may use soothing measures, though the means of action are more limited. It is by the prudently combined employment of purgatives, diuretics, and sudorifics, that we can, by as it were removing the water, take away the serous matters which have a tendency to diffuse themselves throughout the tissues.

Amongst sudorifics, M. Péter emphatically proscribes vapour-baths, which do more harm than good. Dover's powder is a valuable medicine, administered in twenty to thirty centigramme doses, from twice to four times in the course of a morning once or twice a week. The system must be sedulously sustained; for this purpose a sixty-gramme dose of brandy administered in a gum draught is a good tonic; for rich patients, Port, Sherry, or Madeira, either simple or combined with quinine, may be prescribed. Infusion of coffee in medicinal doses, that is to say, half

a coffee cupfull twice or thrice a day, acts beneficially by stimulating the stomach, exciting the nervous system, and even by provoking diuresis; tea being more exciting, and not possessing any diuretic action, is valueless. When the anæmia of the first period has become serious, we must give iron; not in a strong and pharmaceutical form, which would scarcely be tolerated, but as it is supplied by nature in the form of natural mineral waters, above all those of Bussany and Orezza. The latter has the advantage of being subacid and of stimulating the stomach by the carbonic-acid gas contained in it.

Compression should not be employed in the treatment of cedema, as it may bring on both local and general accidents. Trousseau advised the production of artificial eczema by means of frictions with croton oil, but accidents going to the extent of gangrene have induced M. Péter to renounce this plan absolutely, though it has sometimes proved very successful. The only practice adapted for combating œdema is puncture. We must avoid scarifications if possible, as they may bring on gangrene, and even many punctures, which by taking away too much serous matter at one time often occasions unpleasant consequences. Five or six punctures on both feet about every two days are sufficient to relieve the patient, without endangering his safety. As to the medicines which were formerly used against the hypertrophy of the heart, we must abstain from them entirely, the heart having more need to be sustained than weakened.

Hydrotherapeutic treatment constitutes a somewhat heroic method of treating heart-diseases, from which benefit may be derived against the accidents of the third period (visceral congestions) and indeed even in dropsical complications. M. Péter rejects the use of the douche as giving too great a shock, but generally advises the use of cold water, in the first instance applied by the sponge being simply soaked, so as not to allow the water to run down the anterior portion of the body, nor on the posterior portion, which is more impressible by the action of cold water, particularly the back. At the end of a few days, these cold applications are made all over the body, beginning always at the anterior and upper part of the trunk, finally some days further on, when the skin is sufficiently accustomed to it, the water is used with a full sponge, so as to run down the body; the first two or three spongefulls still being pressed out on the anterior part of the body. To further stimulate the skin, a tenth part of alcohol may be added to the water.

Electricity has sometimes yielded good results, but it is as a means which requires further investigation.

M. Péter concludes by some remarks relative to the hygiene for persons attacked by cardiac affections, which may be summed up in the following sentences. Avoid everything which can stimulate the heart to excess, either physically or mentally; follow a good dietetic regimen, tonic and reparative, without being exciting; avoid anæmia; keep up the strength of the heart and of the great vessels. Children should be ordered to take moderate exercise and use cold water to the skin; later on, the choice of a profession should be made, which would neither entail too sedentary, nor too active and exciting a life.

To the young man, M. Péter recommends marriage; but to young women, on the contrary, mar-

riage is dangerous, and pregnancy a peril to be dreaded.

The excesses of the table are always troublesome, particularly in the case of aortic lesions. The food should not be of too exciting a nature; but when the patient has reached the congestive stage, or even more, the dropsical, a kind of dry diet becomes necessary, so as not to augment by the immoderate ingestion of liquids the mass of blood to be moved, and to comfort the heart and vessels. Therefore, no soups or broths should be given, but rather very underdone or even raw meat, seasoned with pickles. If there be anorexia, eggs in all forms, fish, Bourdeaux mixed with a little ferruginous water, and a small quantity of coffee without milk, at the end of the meal, should form the diet. It is necessary that the invalid should have free action of the bowels every day; he must avoid alcoholic excesses, and it is also necessary to prohibit smoking, especially in the form of cigarettes. The patient ought even to avoid frequenting places where there is too much smoke. Coffee taken in large quantities, as well as tea, must also be prohibited. Venereal excesses are to be avoided. The sudden change of temperature occasioned by taking too warm baths, frequenting ball-rooms and theatres, is particularly to be dreaded by sufferers from cardiac disorders.

It is better to live in a valley where the atmosphere is not humid, and which is sheltered from high winds, than on a mountain, in consequence of the greater pressure, and the more considerable density of the air.

Thus all the agencies that can be set at work to palliate the accidents of cardiac affections are passed in review. To the question, Is the malady absolutely incurable? we must answer, as a general rule, Yes, but not in children, in whom a cure may be hoped for if the lesion be of recent origin, and the medical treatment sufficiently active. In support of this assurance, M. Péter quotes the history of a child three years old who had acute rheumatismal endocarditis, with consecutive mitral insufficiency, and who nevertheless recovered. The valvular lesion had been discovered after several weeks, indeed, several months, not only by M. Péter, but by M. Trousseau and M. H. Roger.

The treatment consisted in revulsive and extended applications of tincture of iodine on the chest during the space of several months; and after a long interval MM. Trousseau and Roger were able to affirm that the pathological sounds had entirely vanished.

MEDICINE.

LECTURE ON SPECIFIC OR ZYMOTIC DISEASES. BY DR. WILKS.*

Before taking each of these separately, I shall first speak of them as a whole, and you will then perceive what features they have in common. The most approved theory is that each owes its origin to a specific or peculiar virus, which, being introduced into the system, propagates therein, and reproduces itself to an almost infinite extent. This process is attended by certain characteristic phenomena, and as a rule, the subject of it cannot undergo the process a second time. These facts suggested to Liebig the idea of a fermentation in the blood, whereby a cer-

* *Guy's Hospital Gazette*, January 3, 1874.

tain material (like sugar or starch) might undergo a fermentative change, and that when the process was ended with the destruction of the agent it could never occur again. Upon this hypothesis he framed the word 'zymotic' (*zumoo*, I ferment), a term still retained, although the idea attached to it is not generally held, but used synonymously with the expression 'epidemic.' An explanation by others of a non-recurrence of a specific disease is found, not in the idea of fermentation, but of growth, whereby the virus introduced into the blood grows at the expense of a certain material within it. These two theories, however, may be identical if the growth of the yeast plant and fermentation are considered together.

We use the term 'specific' to designate these diseases, because we believe each one stands isolated from the others, in the same way as a plant or animal is distinguished from all others, as having a different parentage. Just as in the organic world every example of tree or beast produces its like and no other; so amongst these diseases—small-pox produces small-pox, scarlatina produces scarlatina, and none other. Then there is the absolute proof that if the virus of one of these diseases be inoculated into a healthy person a similar affection is produced in the latter. We have, therefore, every reason to conclude that whenever we meet with an example of a specific disease that the germ of the disease has been implanted in the subject of it, just as when we see a weed in our garden we believe the seed must have been sown. There are, also, many other arguments in favour of the belief of the specificity of these diseases, and more especially those drawn from their history in different countries. As, for example, although the climate is the same as it has ever been, yet it was only three years ago that scarlatina appeared in India and parts of Australasia after the arrival of a ship with cases of the disease on board. Small-pox was unknown in America until the conquest of Mexico, when, on being introduced, millions fell victims to its virulence, and the same with syphilis in the Pacific Islands. The importance of these questions arises from the fact that it is only in the minority of instances of specific diseases that we can trace contagion, and yet I must advise you to consider that in every case the disease has been 'caught.' In the present state of our knowledge you have a right to assume that, even though you are unable to prove it, and let the *onus probandi* lie on those who maintain the spontaneous generation of these diseases, as it is for them to prove their position.

You can understand why the specific cause of these diseases is spoken of as a poison, since in the animal and vegetable world a poison means that which produces certain definite and distinctive injurious consequences; so peculiar that when meeting with these symptoms in any individual case, we immediately recognise the causes which are in operation. If, for example, a small quantity of arsenic be administered to a human being he is immediately seized with vomiting, purging, collapse and very definite symptoms; if, instead, he swallowed the cholera or contagium poison very similar phenomena would ensue.

It is, therefore, held that each disease has its cause or active principle, which is called the 'contagium,' and the time may come when a future lecturer may place before his class several bottles labelled 'vaccine,' 'varioline,' 'typhine,' 'cholérine,' &c. That this contagium is not merely a homogeneous fluid, but contains distinct germs, is proved by diluting it, when it is found that after many ex-

perimental trials at inoculation a certain number of these only are successful, showing that these germs are accidentally caught. It is generally believed that these germs are produced in the animal organism, and are therefore living particles or 'zoospores'—that they can only be propagated in the subject of the disease, and therefore it is possible that all these zymotic disorders might be stamped out by isolating patients, just as the cattle-plague is stamped out by killing the animals.

There are those, however, who, holding to the specific nature of the 'contagium,' believe rather that it is of a vegetable kind, and therefore can have an altogether independent existence outside of the animal body. They would contend that the poison of cholera was a rice fungus, that of measles the same as a well-known mould, that typhoid fever poison was produced by vegetable decomposition, and so on. I might also say that those who believe in the spontaneous origin of these diseases are in the minority, but they would hold that typhus fever is produced by overcrowding, relapsing fever by impoverishment, typhoid by vegetable decomposition, cholera by an exaggeration of the circumstances present in our autumn months, scarlatina by decomposition of blood, and even small-pox (according to Miss Nightingale) by bad sanitary conditions. Syphilis would be said also to arise *de novo* from promiscuous intercourse.

I give you these opinions, not with the object of forcing any one of them dogmatically upon you, but that you may know what the theories are, and that you may reason logically and clearly upon them; that you may not raise a cry against the dirty river in your town whenever scarlatina, typhoid or cholera appear, unless you can explain in what way you hold it to be guilty of their production. At present the prevalent opinion would be that the river merely acted as a conveyer of distinct and separate poisons at different times. The proof apparently lies in such an example as is given by the Medical Officer of the Privy Council. A notoriously dirty and ill-drained village, where the wells are frequently contaminated from the offensive ditches, is free for many years from typhoid fever until a case of this disease is brought into the place, when immediately it spreads widely amongst the inhabitants. The means of conveyance is at hand when the poison arrives.

Now let us see what happens when a specific virus is introduced into the system. It immediately infects the blood and commences to produce some change in the way of altering its constitution, whilst it itself is being infinitely propagated. This is the hatching time or period of 'incubation.' As a rule the subject of it is not conscious of the change, and therefore is not ill. When a virus is inoculated we see a local inflammation going on, as after inoculation of small-pox, where the pustule is forming eight days before the constitution is seen to suffer; or after inoculation of syphilis, where an induration goes on at the spot, and after forty days the constitutional symptoms appear. It is most probable that if the virus of other diseases were inserted directly into the system, that the incubating time would be definite, but the mode of and introduction differs in so many ways that this period varies considerably in each particular case. It may be due to the mode in which the virus is introduced, the latter being less able to penetrate the system in one direction than another. Thus small-pox virus inoculated affects the system a few days before it would do so if taken in by the lungs as

vapour; so the secretion of measles acts more rapidly than the vaporous emanations of the skin. I must therefore take the extremest and narrowest limits, and give you the average. The importance of this question is brought before you when you are asked for example, by a mother at what time she is safe from infection after having left nursing her sick child.

When the incubation is complete, the whole body becomes affected by being thrown into a violent febrile state, in which every organ of the body suffers. At the same time the surface of the body, both the skin without and the mucous membrane within, shows marked signs of irritation, and since on those surfaces the poisonous secretions often appear it is thought that the latter are eliminated by these sources. The alterations on these surfaces are peculiar, and more than other symptoms assist us in identifying the disease; such as the peculiar rashes of the exanthemata, and the affections of the ileum in enteric fever. All the solid organs likewise are affected by the poisoned blood, as indicated by their deranged functions seen in the delirium, sickness, diarrhœa, yellow skin, or albuminous urine. The organs are filled with blood, which is often undergoing a solution, and this hæmorrhage occurs within them as well as on the surfaces of the body. We meet, therefore, with what are called malignant forms of the specific diseases in which this hæmorrhagic tendency is often the principal symptom.

I would ask you, therefore, to think of these specific diseases as a whole, by which you may remark in what particulars they resemble one another, and you will not be led into error when a new epidemic arises, either amongst men or the lower animals. You will not assert, because in the rinderpest an eruption is met with, the disease is small-pox; or because ulceration occurs in the intestine that it is typhoid fever; nor will you necessarily think that an epidemic amongst pigs is scarlet fever because the skin is red.

I will conclude with a word about treatment. As far as it is at present known there is no cure for specific diseases; they run their course and cannot be cut short. At least, at the present time there is no evidence in proof of it, although we are constantly trying every new remedy which is suggested for the purpose, such as belladonna for scarlatina, sulphurous acid for typhoid, or sarracenia for small-pox. Whether, after inoculation on the surface of the body, the constitutional disease could be modified by destroying the focus of contagion at that spot is questionable. I am not aware that any experiments were made in rubbing out the small-pox pustule during its development in the time of inoculation, but it was the opinion of Hunter and some modern surgeons as regards syphilis, that the early treatment of an indurated chancre would modify the secondary symptoms. All we do at present in these specific diseases is to assist Nature, and relieve any especially untoward symptoms. We place the patient in as good air as possible, so as to dilute and carry off the poisonous effluvia, and give him cooling drinks. At the same time we may give medicines to relieve a bronchitis or check a diarrhœa, and quite recently it is believed that we may do more than this, for we have begun to regard the increased temperature in the febrile state, not as a necessary part of the process which must be gone through, but as a condition which is positively injurious, and therefore may be checked with advantage. The plan, there-

fore, of placing our patients with typhoid fever in cold baths is undergoing a trial.

| Disease. | Incubation. | Prenatal fever. | Duration of Rash. | Mode of Contagion. |
|------------|---------------------------------------|--------------------|----------------------|--|
| Typhus . | Average 9 days, few days more or less | 4 | 10 | Exhalation from body and lungs, from clothes. |
| Typhoid . | 12-14 days or less | 10 | 14 | Secretion from intestine, inhaled or swallowed. |
| Relapsing | Probably 4-5 days | 17 | | Exhalation from body and lungs. |
| Small-pox | 12 days, when inoculated 8 days | 2 | 8 | Exhalation from body and lungs, from clothes, purulent secretion and scabs. |
| Scarlatina | 3-6 days or less | 1 | 3 | Exhalation from body and lungs, from clothes, blood, epithelial scales swallowed or inhaled. |
| Measles . | 10-15 days, when inoculated 7 days | 3 | 4 | Exhalation from body and lungs, from clothes, blood, secretion from nose. |
| Syphilis . | 30 days | Few days. | Several weeks. | Blood and the various secretions. |

HAYEM ON INJECTIONS INTO THE VEINS IN CHOLERA.—In a discussion upon this subject at the Société Médicale des Hôpitaux (*L'Union Médicale*, 1873, p. 966), M. Hayem stated that the algid stage of cholera might be termed the stage of dehydration, from the rapid loss of liquid, which is the most important pathological change occurring in it. The intestinal lesions are not specific, but are simply catarrhal in character, and their importance consists in their extent and the rapidity of their occurrence, but not in their intensity. They presented the same characters in the recent epidemic as in that of

1865, except that in the latter lesions of Peyer's patches were more marked in children than in adults. Several months ago Messrs. Kelsch and Renaut described a profound alteration of the tubular glands of the intestine in cholera, the whole of the glands, except their bases, being destroyed, and the altered mucous membrane being covered with granulations. M. Hayem has observed on the contrary that the tubular glands are easily recognised, despite a more or less marked alteration in their epithelium. The term granulation also is inexact; for, though the mucous tissue is infiltrated with new elements, there is no new tissue formed. The vessels which are observed are not new, but very old ones, somewhat congested. If granulations were really present, a cicatrix would form during healing; but this is not the case, for the superficial epithelium, which never desquamates completely, is regenerated, and the exudation-products and lymphoid corpuscles are absorbed, just as in catarrhal inflammation. During the period of reaction, danger does not arise from the persistence of intestinal lesions, but from the changes which the blood has undergone in consequence of its stasis; and this period might therefore be termed that of secondary toxæmia, just as the first was called that of dehydration. The stasis having passed off and circulation again begun, the organs become supplied with blood having an abnormal composition, and in consequence the functions of the kidneys, brain, and circulating apparatus, become disturbed, and cutaneous eruptions make their appearance. It is uncertain what the changes are which the blood has undergone during the period of stasis; but M. Hayem recalls the observation of Schiff, that a ferment which transforms the glycogen of the liver into sugar, and thus induces glycosuria, becomes developed during stasis. Besides this, there occur in the blood certain morphological changes consisting in the presence of small red globules in it; which were formerly observed by Hayem and Henocque, and afterwards by Kelsch and Renaut. The latter authors think that they are red corpuscles which have become desiccated and contracted. M. Hayem, however, considers them to be broken red corpuscles. During stasis, the red as well as the white corpuscles pass through the vascular walls, and some of them, sticking half-way through, are broken by the force of the current when the circulation recommences. He is able to obtain these broken corpuscles by producing stasis in the limb of a guinea-pig by means of a ligature. Stasis is, according to him, very important, as it is the cause of changes in the blood. The object of the physician ought, therefore, to be either to prevent it or to limit its duration and extent. Injections into the veins are usually employed too late; they ought to be tried at the commencement of stasis, and before the toxæmia which results from it has been produced.

T. LAUDER BRUNTON, M.D.

VALLIN ON ENTERIC FEVER WITHOUT ANY ELEVATION OF TEMPERATURE.—The utility of the clinical thermometer in the diagnosis between different fevers has probably been exaggerated. For example, few physicians who have had extensive experience of enteric fever would subscribe to the dogmatic assertion of Wunderlich, that no fever can be enteric fever, on the fourth day of which the evening temperature does not reach 39.5°C . or 103.5°Fahr . It is, however, a point on which most observers are agreed, that the thermometer is of the greatest pos-

sible use in settling the question whether the febrile state exists or not. It is now admitted that there may be fever without any increase in the frequency of the pulse, but that there can be no fever without elevation of temperature; and conversely that, when the temperature is elevated, there is fever. From this point of view, there are no circumstances in which the thermometer is oftener resorted to with advantage than in the diagnosis of mild cases of enteric fever, and particularly of those cases which German writers have designated *typhus ambulatorius*, from the fact of the patient's continuing to go about throughout the whole or greater part of the disease. But Dr. Vallin, in an article on the ambulatory or apyretic form of typhoid fever (*Archives Générales de Médecine*, November, 1873), tells us that enteric fever, even in its gravest form, may run its course without any elevation of temperature; and it is clear that, if this statement be accepted as correct, the physician is deprived of a most material aid to diagnosis, under circumstances where a correct diagnosis is of the utmost importance. It is precisely in these cases that a knowledge of the temperature-range has been thought to be of the greatest value. Before, therefore, accepting Dr. Vallin's facts, it is necessary to submit them to careful criticism.

Dr. Vallin refers, in the first place to the cases of *latent* enteric fever, recorded by Louis, Griesinger, Trousseau, and other observers; but from all these cases he considers that his differed in the circumstance, that for fifteen days the temperature at no time exceeded 37.6°C . or 99.7°Fahr . The cases which he records in support of this remarkable statement are two.

One was that of a man, aged thirty-six, who first came under observation on December 13th, 1872, and whose temperature was first taken on the following day. When he was first admitted into the hospital, he was extremely emaciated and weak, as if he had already passed through a protracted illness, and while in the hospital he had diarrhoea, colicky pains in the abdomen, and albuminous urine. On December 22 he died, and, until within a few hours of death, when symptoms of peritonitis set in, and the temperature rose to 39.4°C . or 102.9°Fahr . the morning and evening temperatures never exceeded 37.6°C . or 99.7°Fahr . After death, the intestinal lesions of enteric fever were found in conjunction with recent peritonitis. [In reference to this case, it is necessary to observe that, although the patient had not been entirely confined to bed prior to admission into hospital, he had been taken ill on November 15th with malaise, lassitude, and loss of appetite, and that from December 1st he had been obliged to give up his work, his appetite had entirely failed, and his prostration had daily increased. He had therefore been ill for twenty-nine days, and had passed through the primary fever, before his temperature was ever taken; and when admitted into hospital he was merely suffering from the prostration consequent on the febrile attack, and from symptoms due to the intestinal lesion, which, as often happens, persists and may advance to perforation, long after the primary fever has ceased. The case is far from being an uncommon one, and cannot legitimately be adduced as an instance of enteric fever running its course without any rise of temperature.—*Rep.*]

The other case was that of a man, aged twenty-four, whose temperature from the seventh day of the attack (on which it was first taken) was taken night and morning, and for twelve days never exceeded 37.4°C .

or 99.3° Fahr. The symptoms were evidently of a mild nature until the eighteenth day, when the patient suddenly passed into a state of alarming collapse, due to intestinal hæmorrhage, from the effects of which he narrowly escaped. On the occurrence of the hæmorrhage, the temperature fell to 36.4° C., or 97.5° Fahr., but next day it rose to 39.6° C., or 103.3° Fahr., and for many days it remained higher, the evening temperature on the thirty-second day being still 39° C., or 102.2° Fahr., the pyrexia being probably maintained by sloughing of the integuments on the sacrum.

In this case, the circumstance of the temperature between the seventh and eighteenth days of the disease having never been found to exceed the normal standard, is probably accounted for by insufficient observation. The temperature was only taken twice during the twenty-four hours; and, although the author is of opinion that it could not have risen materially in the intervals without the patient being sensible of the change, our experience is entirely different. The case was evidently one of those cases of enteric fever which have been familiar to all students of the disease since the date of the first edition of Louis's great work, and which run a very latent course until copious hæmorrhage or acute peritonitis suddenly supervenes, and converts what apparently has been a trivial malady into one of the most formidable with which we have to cope. In these cases the febrile paroxysms may occur during the day, and be so brief that they may fail to be discovered, unless repeated observations of the temperature be made. The fever, which in most cases is remittent, is here intermittent. Cases answering to this description have been not uncommon in our practice, and have been recorded by Griesinger, and other authorities.

[For these reasons, we are unable to accept Dr. Vallin's cases as proving that enteric fever can run its course without any rise of temperature, or as in any way tending to depreciate the value of the thermometer in the diagnosis of disease.—*Rep.*]

C. MURCHISON, M.D.

OBSTETRICS AND GYNÆCOLOGY.

DUNCAN ON THE HÆMORRHAGE DURING PREGNANCY IN CASES OF PLACENTA PRÆVIA.—Dr. Matthews Duncan maintains that the ordinary theories on this subject are incorrect. They are—1. That hæmorrhage occurs from the gradual expansion of the cervix as pregnancy advances, because it is now generally admitted that the cervix is not really taken up to form a portion of the uterine cavity; 2. That it occurs from separation, because the lower part of the uterus was specially developed in the latter months, while the placenta ceased to grow in proportion; 3. The converse theory, more recently advocated by Barnes, is that the disproportionate growth was on the part of the placenta. After giving his reasons for not agreeing with any of these views, Dr. Duncan proposes his own theory, which is that these hæmorrhages are not truly unavoidable but accidental, and that their occurrence is favoured by the extraordinary anatomical conditions occurring in placenta prævia, as well as by other circumstances, such as the increased pressure of blood above what exists in ordinary situations of the after-birth. He considers, therefore, the whole pa-

thology of placenta prævia to be nearly, if not quite, identical with that of accidental hæmorrhage. He states, also, that there are four ways in which hæmorrhage during pregnancy may occur:—

1. By rupture of an utero-placental vessel at or above the internal os uteri. This is analogous to the source of hæmorrhage in some cases of uterine fibroid or polypus.
2. By rupture of a marginal utero-placental sinus within the area of spontaneous premature detachment, where the placenta is inserted, not centrally or covering the internal os, but with a margin at or near the os.
3. By partial separation of the placenta from a jerk or fall.
4. By partial separation of the placenta, in consequence of uterine pains producing a small amount of dilatation of the internal os. Such cases may be otherwise described as instances of miscarriages commencing but arrested at a very early stage.

W. S. PLAYFAIR, M.D.

LEOPOLD ON THE LYMPHATICS OF THE NORMAL NON-PREGNANT UTERUS.—Dr. G. Leopold has arrived at the following conclusions with regard to the lymphatics of the normal non-pregnant uterus (*Archiv für Gynæcol.* vol. vi.).

1. *Mucous Membrane.*—1. The mucous membrane consists of a framework of the finest connective tissue, the bundles of which are covered with endothelium, and whose interspaces form the lymph-spaces (*Lymphräume*). 2. In the deeper layers, the membrane of the glands consists of a fine layer of delicate connective tissue bundles, whose epithelium lies externally, but more superficially it is formed only of a sheath composed of the cell-plates (*Zellplatten, plättchenförmigen Zellen*). 3. The blood-vessels, from the finest capillaries onwards, have a number of fine endothelial sheaths increasing with their size. 4. The framework of connective tissue stands by means of fine twigs in direct connection with both sorts of sheaths. 5. The glands and blood-vessels, therefore, pass directly through the lymph-spaces, separated only from the latter by their sheaths, formed from the framework of connective tissue. 6. At the limits of the muscular layer, the lymph-spaces reach a short distance into the filter-shaped hollows between the muscular bundles, and become gradually narrowed into the intermuscular lymph-vessels and spaces.

II. *Muscular Coat.*—1. The muscular layer contains in animals and in the human subject lymph-vessels and lymph-spaces (*Lymphspalten*). The walls of each are formed of the fine intermuscular connective tissue. The former are lined by fine endothelial lamellæ, which exhibit here and there openings and slits; the latter are lined by delicate cell-plates (*Zellplatten*). 2. In animals, the characteristic net of lymphatics is arranged parallel to the long axis of the two layers of fibres; they, therefore, cross each other. Those of the inner layer pass into the lymph-spaces of the mucous membrane, and those of the outer into the subserous lymph-vessels. The large lymph-collecting tubes, provided with valves, and spread in the form of a net over the horns of the uterus, lie between the muscular layers, and receive the whole lymph-vessels from both sides: externally those of the subserous and outer muscular layers, and internally those of the inner layers and the mucous membrane. 3. In the uterus of the human subject the lymph-vessels are much more

complicated, on account of the arrangement of the muscular fibres. They are most richly developed in the outer layer, and in the other layers specially in the neighbourhood of the large vessels, and are connected with the subserous membrane as in animals, but with the mucous more by lymph-spaces. They come together in the outer layer, especially at the side of the uterus. 4. The lymph-spaces, in the human subject and in animals, surround the smaller bundle of a large muscular bundle, and pass into the lymphatics. In animals, they stand in indirect connection with the subserous and mucous channels; in the human subject, however, in direct connection. 5. For the most part, large blood-vessels lie in the neighbourhood of the large collecting tubes; the other lymph-vessels are partly accompanied by blood-vessels for a certain distance, and the lymph-spaces are almost regularly penetrated by small vessels.

III. *Serous Coat*.—1. Under the serous membrane, only lymph-vessels are found. They lie in the subserous connective tissue, and form large characteristic nets. 2. They are much less numerous than the subserous blood-vessels lying over them, but are from eight to ten times stronger than the latter. 3. They have large ampullæ, points of union, constrictions, valves, and swellings, and send branches towards the deeper parts, either in a vertical direction or at an angle. 4. In the pig, rabbit, and sheep, the net has mostly a direction corresponding to the long axis of the uterine horns. In the human subject, on the contrary they cover the anterior and posterior wall, in irregular large or small groups, and have, especially at the insertion of the Fallopian tube, large ampullæ, and then pass as an extended net upon the tube.

WILLIAM STIRLING, D.Sc., M.B.

MISCELLANY.

WHAT IT COSTS TO SUPPORT HOSPITALS IN NEW YORK CITY.—According to the official estimates for 1873 we have the following: *Department of Charities and Corrections*.—Out-door Poor Department, \$128,066; Bureau of Out-door Sick Poor, \$5,300; Bellevue Hospital, estimated number of patients, 700, \$103,370, or \$147.67 each patient; Charity Hospital, estimated number of patients 950, \$133,302, or \$140.31 each patient; Hospital for Contagious Diseases, 180 patients, \$20,667; Fever Hospital, 60 patients, \$6,179; Small-Pox Hospital, 75 estimated inmates, \$24,950; Hospital for Incurables, \$13,393; Asylum for the Blind, 150 inmates, \$8,055; Convalescent Hospital, 250 inmates, \$22,041; Lunatic Asylum, 1,300 patients, \$119,919, or \$92.25 per patient; New York City Asylum for Insane, 650 patients, \$83,026, or \$127.72 per patient; Hospital for Epileptic and Paralytic Patients, 120 patients, \$13,172; Hospital for Infants, 450 children, \$51,780, or \$115.06 per child; Randall's Island Nurseries, 650 inmates, \$61,282, or \$93.58 per inmate; Nursery Hospital and Idiot House, Randall's Island, 450 inmates, \$47,887; Inebriate Asylum, \$23,611; Reception Hospital Centre Street, \$10,180; Reception Hospital, 115th Street, \$5,920; Ambulance Establishment, \$3,995; General Drug Department, salaries, \$2,500. Total, \$888,595, as the estimate for the above hospitals, &c., Department of Charities and Corrections.

EATING TOO MUCH.—It has been lately pointed out that while many people doubtless do eat too much, that some are over-anxious lest they should err in that direction. The following passage, from the translation of a recent paper by Dr. Max von Pettenkofer, supports this view.

'It is only a short time ago that it was customary in physiology to speak of a superfluous or luxurious consumption. According to certain physiologists, as long as the body is able to perform its functions, even though suffering from hunger, to take more food was luxury. But Bischoff and Voit fully demonstrated by their experiments on nutrition that the result of a nourishment so restricted is a state of want—a continual famine incompatible, in the long run, with the normal conditions of life. The body has need of a certain well-being—of a small excess of nourishment in order to preserve its strength and vigour. What just prevents death from hunger is not sufficient. It is as if we were to restrain the organism from producing any more heat than suffices to prevent death from cold, under pretext that all beyond this limit was superfluity and luxury.'

A RACE OF DWARFS.—The Geographical Society of Italy has received from Alexandria, with the news of the death of the explorer Miani, and various ethnological objects, two living individuals whom he had forwarded of the tribes of the Akka or Tikku-Tikki, and whom the learned traveller had bought of the King Munza. These individuals—of whom one is eighteen years old, and forty inches in height, and the other sixteen and thirty-one inches high—are stated by Miani to belong to the race of dwarfs described by Herodotus, and recently rediscovered by the German explorer Schweinfurth, who described them carefully. They are pot-bellied, very thin-limbed, and knock-kneed, spherical and prognathous crania, very long limbs, copper skins, and crisp, tow-like hair.

A HOSPITAL FOR HYPOCHONDRIACS.—The late Seth Adams, of Massachusetts, who left an estate of \$1,701,000, has provided in his will for the establishment, within fifteen miles of Boston, of an asylum for the treatment of hypochondriacs. Mr. Adams had himself suffered from hypochondria for many years.

EPSOM SALTS.—The human race will shortly be purged at a much cheaper rate than heretofore. We learn from *L'Union Médicale* that an enormous deposit of Epsom salts has been discovered at Alcanadre (Spain), in a district traversed by the Tudela railway.

PROFESSOR DONDERS shows that the time occupied in the transmission of a sensation through the eye to the brain, the formation of a judgment, and the transmission of a volition from brain to hand is .15 of a second; but when the ear is the receiving organ the time required is only .09 of a second.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, JANUARY 21, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

LANGENBECK AND OTHERS ON BLOODLESS OPERATIONS.

In the *Berliner Klinische Wochenschrift* of December 29, 1873, is published a communication by Baron von Langenbeck to the Berlin Medical Society, on Esmarch's method of 'bloodless operation.' He remarks that by this method the loss of blood in operations on the extremities may be reduced to a minimum, or, to speak more correctly, the operation may be throughout performed bloodlessly (*unblutig*). Attempts to control the loss of blood by compression of the limb are not new. For many years Langenbeck has been accustomed to bandage the extremity from the toes upwards with a wet bandage firmly applied, and then to put on a tourniquet above, before amputating the thigh, in cases of weak patients where loss of blood was to be feared. Other surgeons might have done the same thing; he did not claim priority. A great advantage of Esmarch's method, besides the saving of blood, is that the field of operation is never obscured, and the anatomical and pathological relations of the tissues may be inspected with the greatest facility. In delicate operations, as for instance, the resection of the wrist, any needless injury of the tissues may be certainly avoided, without constantly mopping up the blood, or injuring the wound with sponges. On the removal of the constriction the skin becomes red, as if stricken with erysipelas; capillary bleeding occurs, supposing the larger vessels to be tied, somewhat more copiously than usual, but no disadvantage appears to follow. Professor Langenbeck suggests certain precautions which should be borne in mind in the use of this means. In the first place, it is doubtful if the constriction should be employed where the parts are filled with pus, because possibly the infiltrated matter might be pressed into the circulation; the same remark applies in cases of amputation performed for soft tumours, or those affected by gangrene; and in the upper extremity the constriction of the India-rubber tube may perhaps give rise to paralysis of the median or ulnar nerves, by compressing them against the bone. In two cases Langenbeck has observed branches of the median nerve affected in this way. In one case the paralytic symptoms disappeared in fourteen days; and in the other, in which complete motor paralysis of the median nerve had taken place, after the lapse of three weeks, when the patient was leaving the hospital, the effects still remained. To avoid such mischances, Langenbeck no longer uses the elastic tube in operations on the upper extremity, but, in place of it, he applies, after the peripheral bandaging has been

accomplished, a second elastic bandage round the upper third of the arm. With this modification he has performed resection of the wrist-joint and several other operations just as bloodlessly as if the tube were employed, and without any subsequent interference with the nervous functions.

Dr. Brandis of Aix-la-Chapelle has published some observations on this subject. He attaches the greatest importance to Esmarch's invention. The idea of emptying a part of the body of blood before operating is perhaps not new. Desmarres' eyelid-forceps is an example; but he considers that the merit of keeping large portions of the body empty of blood, even two extremities at the same time, without injury to the general circulation, and during the entire continuance of a perhaps tedious operation, belongs to Esmarch alone.

In the first case, one of removal of sequestrum from the tibia, in which Dr. Brandis tried the method, he was surprised at the rapid healing of the wound. The next case which he relates was a resection of the wrist-joint, performed in the usual way; the patient did not do well, and it became a question of amputation of the forearm. Just at this time he became acquainted with Esmarch's method, and believing it would afford facilities in the examination of the diseased joint, he performed a second operation for the removal of diseased bone. It is unnecessary to give the steps of the operation, but the result proved highly satisfactory. The operation was performed easily, and all the tendons were preserved uninjured. Only trifling local or general reaction followed the operation, and this is ascribed in great part to the absence of any loss of blood. The patient was a feeble exsanguine man.

He then compares the two operations as performed on the same joint. The first was unsatisfactory, very bloody, and followed by severe fever, lasting five days, and by moderate fever for three weeks, and also by several abscesses. The second operation lasted an hour and a quarter, produced a very large wound, was accomplished without loss of blood, and resulted in the preservation of an useful hand; the traumatic fever was slight, lasting barely three days, and the patient scarcely suffered anything. Another not less satisfactory case of resection of the elbow-joint is detailed. But Esmarch's discovery, Dr. Brandis continues, does not merely apply to the great operations of surgery. Who has not been, for instance, in the painful position of hopelessly seeking for a piece of needle broken off in the palm of the hand or foot? Perhaps at first it was possible to feel the point of the foreign body from without, quite easily; the surgeon cut down upon it, and suddenly everything was changed, the needle had disappeared, and the wound was full of blood. Then followed sponging and examination with the finger, sound, or forceps, but all in vain. Once and again the forceps seem to have caught hold of something hard; but, on pulling it steadily one became convinced that it was palmar or plantar fascia, or something lying deeper, but not the needle. Too often the search is in vain, and the result, a deep, painful, protracted suppuration. Dr. Brandis has recently had occasion to satisfy himself how very differently and how more easily such an exploration may be now made.

Dr. Leisrink of Hamburg, in a critical notice of Professor Esmarch's paper in Volkmann's *Sammlung*, says that from the day when Ambrose Paré ligatured arteries, and no longer cauterised amputation-stumps, science received a new impetus. The

first joint-resection proved the beginning of an entirely new development of operative surgery, and the first bloodless operation will also have disclosed an entirely new point of view, with regard to operations on the extremities, and serve for the heading of a new chapter in the history of surgery.

The first time he saw the method used, was in a case of the ligature of the anterior tibial artery; and in the deep wound that was necessarily made, not a drop of blood obscured the steps of the operation.

The following are the advantages which Leisrink attributes to the use of Esmarch's apparatus.

1. The patient will in future preserve the blood formerly lost during operation, and in the amputated limb.

2. On this account, healing of the wound will be quicker.

3. In all probability, there will be fewer chances for the inception of traumatic diseases.

4. The operator will be often spared the need of an assistant, and may complete his operation much more quickly.

Perhaps there may be other advantages or disadvantages which longer experience will discover; meanwhile, he is convinced that the time will soon come when Esmarch's apparatus will be found amongst the instruments, not merely of every hospital, but of every practising surgeon, just as often as a tracheotomy-tube, or a hernia-knife.

WILLIAM MAC CORMAC.

EXNER ON THE TIME OF REACTION OF THE SENSORIUM.

When some phenomenon of the external world affects one of the senses, a determinate short time elapses before the impression is perceived by the observer, and responded to by him with a signal. This time is different for different individuals; the difference is denoted scientifically by the expression 'personal equation.' Donders some time since made experiments on the subject; and it has recently been investigated anew by M. Exner (*Archiv für die gesammte Physiologie*, vol. vii. p. 601).

M. Exner names the time elapsing between the impression of a stimulus on the organ of sense and the conscious reaction, the 'reaction-time.' He sought to determine the length of it for various individuals, for various organs, and under various circumstances. The consciousness of the stimulation was generally indicated by the right hand pressing a key. The motion of this, as also the stimulation, produced marks on a rotating blackened cylinder; and from the known rate of rotation, and the space between the two marks, the interval of time could be estimated.

Experiments were first made on seven persons, of different character and age (one of them a frail old man of seventy-six); the time being noted which they took to make a signal with the right hand, when the left was stimulated by an induction-shock. The tabulated results show great differences in the reaction-time (minimum '1295 second, maximum '3576 second.) Nor did they seem to depend on age. 'So far as my experience goes (which is, indeed, limited), it seems to me that the shortest reaction-time may in general be looked for in those individuals who are most accustomed to concentrate their attention on an object, and that those who let their ideas run loosely have a greater reaction-time, whether they are young or old.' It is clear that the differences lie quite beyond the limits of error.

'It is striking to any one who makes these experiments for the first time, how little he is master of his movements, when the point is, to produce them as quickly as possible. Not merely the violence of contraction (*Zuckung*) lies greatly beyond the domain of choice, but also the time at which the contraction is produced is to a certain degree independent of us. We make a contraction, and can afterwards tell, with surprising accuracy, whether we have done it sooner or later than at another time; but we really have not the power of reacting at a desired moment.' An approximate explanation of this may be found in the following observation.

'One feels in the sensorium, while he is with tense attention expecting the stimulus, an indescribable something, which tends to produce (*besorgt*) the quickest possible reaction. If the sensorium be in this state, the reaction is, if I may so express it, involuntary; that is, there is not required an additional impulse of will, after stimulation occurs, in order to the reaction; and, on the other hand, it requires a measurable time to restore this condition; and if the stimulation take place before this has been done, there still occurs here also a contraction without will (so to speak). That, therefore, which causes that the reaction should occur after stimulus, consists in a central change which has already appeared before the stimulus is applied. It is this change which is voluntarily produced.'

For the success of these experiments on reaction-time, a high degree of attention is necessary. If this become sluggish, large and discordant figures are obtained. That the attention, therefore, might not be needlessly wearied, the time was vaguely indicated at which the individual would receive a stimulus. Exceptionally short reaction-times are obtained when the stimulus is strong, and the person is startled.

The reaction-time measured by different methods gives corresponding results for different individuals; that is, if one mode of measurement give with one individual a smaller number than another mode, that mode will give with another individual a smaller number than the other mode. The tables further show that the shortest reaction-time is got by the mode of measurement, in which the stimulus used is a light-flash produced by sending an induction-shock through the eye. The stimulus giving the next shortest reaction-time is an electric shock to a finger of the left hand; then follow, in order, the hearing of sudden sound, electric shock to the forehead, shock to a finger of the right hand, sight of an electric spark, finally a shock to the toes of the left foot. [Donders measured the time for three of these cases, and found the same order.]

Of the circumstances which affect the reaction-time, the most important is the intensity of the stimulus; weak stimuli give badly agreeing, and, in general, larger numbers than strong stimuli. Then there is the attention already referred to. The reaction-time, further, diminishes with increasing practice. Fatigue, however, has an opposite influence. In the course of a long-continued series of experiments, the last results show generally larger numbers than the first. After drinking two bottles of Rhine wine, the reaction-time rose from '1904 second to '2969 second. The taking of tea or of a small dose of morphia had no effect.

M. Exner next proceeds to the analysis of the reaction-time, and resolves it into the following seven 'moments;' 1. The time which elapses while the sense-apparatus translates the active *vis viva* into a

nerve-stimulus; 2. The time in which the stimulus passes along the nerve to the central nerve-system; 3. The time in which the stimulus traverses the spinal cord; 4. The time of central exchange for a motor stimulus; 5. The time of return along the spinal cord; 6. The time of conduction in the motor nerves; 7. The time of setting free (*Auslösung*) the muscular motion. Nos. 1, 3, 4, and 5 are specially considered; the others have been fully studied by Helmholtz and others.

Of special interest is the first question: How long does the organ of sense require for transformation of external force into nerve stimulus? For the answer of it, only the experiments with sight were available. The reaction-time, when the nerve is stimulated by light (as in seeing an electric spark), is compared with that obtained from direct stimulation of the optic nerves by an electric shock; and the difference may be considered as indicating the time which the retina requires to translate the impression of light into a nerve stimulus. The experiments showed that the reaction-time on seeing an electric spark, is about '1506 second; while, with direct stimulus, it is '1139 second. They further showed that the reaction-time in the former mode, if the intensity of the spark be increased, may descend to '1229 second: but in direct stimulation of the retina, the minimum was yet considerably smaller, only '1007 second. We can, therefore, only accept as certainly probable the existence of a latent stimulation; 'that is, that after the image of the electric spark is formed on the retina, a moment occurs, in which the nerve-tissue is preparing the forces applied to it, but has not so far prepared them that they can produce an excitement of the nerve. In what form are these forces present in the retina, when they are no longer light, and are not yet nerve-excitation? This is not an uninteresting problem, the solution of which, however, we must unfortunately give up.'

As to the conduction of sensory and of motor-excitation through the spinal cord, the experiments showed that the sensory velocity of conduction was about 8 mètres per second, while the motor conduction was 11 or 12 mètres. These values are to be taken as merely approximate; but it clearly appeared that the conduction in the spinal cord is considerably slower than in a peripheric nerve.

The central exchange of the sensory stimulus for the motor, or the 'reduced' reaction-time, embraces those phenomena of the entire circuit which occur in the brain, and they are calculated from the reaction-time, by deduction of the time taken for conduction beyond the brain. All the circumstances above specified as influencing the reaction-time have influence also on the 'reduced' reaction-time; viz., attention, strength of stimulus, and practice.

As to the influence of practice, which, in the case of the old man, brought down the reaction-time from '0426 to '1340 second in the course of a few months, the striking fact is observed, 'that the diminution of the reaction-time is not continuous, perceptible from experiment to experiment, but that it takes place in springs, and that these springs occur in pauses between the series of experiments. Thus the old man learned to react more quickly in the course of days on which he made no experiments. This behaviour is much too obvious to be attributed to accident. It has, moreover, appeared to me that our daily life affords experiences according to which something similar occurs in bodily exercises.'

Different results from those above described (the author points out) are obtained, where one is required, not to answer a sudden stimulus, but to give the moment at which a phenomenon, previously followed, passes into a particular stage, e.g., when a star crosses the wire of a telescope. It is not, properly, the reaction-time that is here determined, but the capability of the brain to measure the time of entrance of a phenomenon. While in this case the possibility presents itself of the coincidence of reaction with impression of the sense, it is also possible, on the other hand, that the reaction may occur earlier. In fact, the many experiments hitherto made on this—measurements of the 'personal equation' by astronomers—give both positive and negative divergences, which are much more considerable than those found in measurement of reaction-time. The old methods of determining the personal equation are not so well adapted for the purpose as that here described.

ALEX. B. MACDOWALL

FORSTER ON THE SIGNIFICANCE OF THE ASH-CONSTITUENTS IN FOOD.

J. Forster (*Zeitschrift für Biologie*, vol. ix.) has selected pigeons and dogs for his experiments on this subject. These animals were fed with food containing as few salts as possible, 'with albumen, in the form of the residue of flesh after the preparation of the "extract of meat." This residue, as is known, is not quite free from salts, but these were extracted from it, as far as possible, by repeated boiling and washing in distilled water. By this process a powder, containing in the dried state 14.445 per cent. of nitrogen was obtained; 100 grammes of this dried substance contained—

| | | |
|---------------------------|---------|---------|
| Phosphoric acid anhydride | . 0.548 | gramme. |
| Chalk (calcium oxide) | . 0.078 | " |
| Iron | . 0.023 | " |
| Potassium | . 0.151 | " |
| | 0.800 | " |

Magnesia and chlorine were found in too small quantities to be weighed. Casein from ordinary milk, boiled in distilled water, was also employed. The starch used was treated several times with a 0.08 per cent. solution of hydrochloric acid, and washed in a filter with distilled water until the filtrate yielded no precipitate on the addition of nitrous acid. A mixture of one part of casein and seven parts of starch, as used in the experiments on the pigeons, contained 0.279 grammes of phosphoric acid in 100 grammes of the dried mixture. Fat, in the form of the best butter, formed part of the food, and in addition distilled water was freely given.

A prepared mixture of the above was given to pigeons and dogs, and when it was rejected they were fed artificially. The author concludes from his experiments that the addition of certain salts is necessary for the retention of the balance of materials (*Stoffgleichgewicht*) in the animal economy. When this supply sinks below a certain limit or is completely withdrawn, the body excretes salts, and the animal dies.

The following table shows the quantity of nitrogen taken in in the food, and that excreted, in a dog. The duration of the experiment is divided into three periods of eight days each.

This table clearly shows that the removal of salts from the food has no effect on the transformation or albumen, but that this chiefly depends upon the quantity and kind of supply of the combustible alimentary materials.

| TAKEN IN | | | | NITROGEN EXCRETED | | | NITROGEN DIFFERENCE. |
|------------|-------|--------|----------|-------------------|-------|-------|----------------------|
| Flesh | Fat | Starch | Nitrogen | Urine | Fæces | Total | |
| I. 1,433 | 1,200 | 300 | 207.0 | 197.5 | 7.5 | 205.2 | +1.8 |
| II. 1,311 | 650 | — | 189.3 | 188.2 | 15.0 | 203.2 | -13.9 |
| III. 1,249 | 689 | 663 | 180.4 | 182.1 | 16.0 | 198.1 | -17.7 |

Apart from the contents in salts, the solid as well as the fluid products excreted, during deprivation from salts, are the same as in normal nutrition. At the beginning of the experiments, the digestive juices secreted had the normal constitution, but they gradually changed. A time then arrived when they became inactive, or no longer had the normal composition.

In all animals fed with food from which the salts had as far as possible been extracted, a condition of weakness of the muscles and tremblings occurred, best characterised as general exhaustion. The weakness of the posterior limbs of the dogs assumed in the second week of the experiments a paralytic character. The activity of the brain was disturbed, as shown by the stupid appearance of the animals, etc. Phenomena of increased sensibility showed themselves later. By the greatest possible removal of the mineral constituents from the food of adult animals, the process of the changes of materials and decomposition in the body proceed in the same way, till the death of the animal, as by a diet which, in addition to the above necessary constituents, also contains the ash constituents. Latterly, however, disturbances in the functions of the organs occur, which hinder on the one side the transformation of the nutritive material into modifications capable of being absorbed, and thereby prevent the reparation of the decomposed material of the body, and on the other, by suppression of processes necessary to life, bring about the destruction of the organism, before the impossibility of a continued reception of food is followed by decline and death.

With regard to the salts excreted, when these are removed from the food, the table shows that the excretion of phosphoric acid is never interrupted. In animals deprived of salts, the excretion of this substance by the urine is largely diminished. The less the quantity of food poor in salts introduced, the greater is the loss in phosphoric acid which the body suffers. The smallest quantity excreted corresponded to the time when the greatest quantity of combustible material was introduced.

Although the food was quite free from chlorine, and the urine in the latter period of the experiment contained only a trace of this substance, still the vomitings on the thirty-fourth day showed that a large quantity of chlorine was mixed in the stomach with the food introduced. 246 grammes of food vomited contained 1.63 grammes of chlorine, while the urine excreted on the same day contained only 0.04 grammes. Chlorine was continually excreted in the stomach and absorbed again, for the fæces contained no chlorine.

The author thinks that all these conditions are to be explained by the condition of the salts in the body. He divides these into two classes. By far the greatest

part is in combination with the combustible substances, chiefly with the albuminous bodies in fixed or loose combinations. A small fraction, previously in combination, but freed by decomposition and oxidation, is present in the blood, with the products of the metamorphosis of the tissues. The latter are excreted on the blood passing through the kidneys. Food free from salts, introduced into blood from the digestive canal, unites in the blood with the free salts arising from the chemical decompositions. The quantity of salts excreted must increase with the quantity of free salts in the blood. The salts excreted are increased during hunger, and this because the salts in combination with the body-substance are set free to enter the blood. An increased excretion was also observed when a surplus of salts was added to the food, as was the case at the end of one experiment.

The author is of opinion that the supply of nutritive salts, or of those salts in the food which can prevent a loss of salts from the body, is less than till now has been supposed.

WILLIAM STIRLING, D.Sc., M.B.

MEDICINE.

LECORCHÉ ON THE SECONDARY PART PLAYED BY GLYCOSURIA IN DIABETES MELLITUS.

It is now some time since Trousseau's clear insight foresaw that, in diabetes mellitus, the glycæmia which brings on glycosuria is not really the disease. As M. Claude Bernard has since demonstrated in his lectures, the glycosuric phenomenon must only be regarded as an effort of the organism to regenerate itself, and as the expression of a salutary physiological tendency. The true etiological element, says M. Bernard, is the cause, at present unknown, which brings on the primitive weakening of the organ. This cause reacts on the liver, produces glycæmia, and brings on a powerful reaction in all the reparative organs. But this action ends by exhausting itself; the glycæmia itself finally diminishes when the too persistent diabetes has exhausted the organic effort which tended to regeneration. The practical deductions from these conclusions, arrived at by a learned and able observer, are immediately perceived.

Dr. Lecorché has turned his attention to this subject, and made a critical examination of the various methods which erroneous theories have extolled as remedies against glycosuria, and which can only give very incomplete and merely temporary cures. In the most successful cases of patients apparently cured because they ceased to be glycosuric, they none the less died diabetic; that is to say, azoturic.

Forming the therapeutic means generally recommended into three groups corresponding to the so-called rational theories of diabetes mellitus, M. Lecorché shows the inadequacy of these remedies; and, from this point of view, first makes an estimate of M. Bouchardat's well-known practice, which consists in preventing the introduction of the glyco-genous element into the animal economy by the suppression of starchy foods, sugar, and saccharine fruits, alcohol, and, in fact, everything which would appear to favour the development of sugar. M. Lecorché, however, says that this suppression is not

merely useless ; for, even if it possess the slight advantage of not overloading the system with original matters which are not consumed, it sometimes—nay, very often—proves very injurious to the patient.

When strict note is taken, it is not uncommon to find the stomach become intolerant of an exclusively nitrogenous regimen, whence arises dyspepsia ; the absorption of the ingested substances is only partially accomplished, and the anæmic condition, which is common after digestive disturbances, makes its appearance. This anæmic condition is the more serious in this case, because it favours the malassimilating process which constitutes the foundation of diabetes. Besides this, the local conditions may be against the application of the regimen, to which patients deprived of starchy matters are submitted. Some patients at a certain stage of their disease cannot tolerate any of the gluten breads generally ordered—viz., those patients whose powers of mastication are impaired by dental caries or by the attacks of stomatitis, which are frequent in the course of this disorder. The feculents ought not to be suppressed, for their suppression has only one advantage, that of not overloading the circulatory system with useless matters destined to be partially rejected in the shape of grape-sugar. This advantage, however is on the whole but of very slight importance ; and if the disagreeable consequences which may result from the suppression of this kind of food be taken into consideration, it will easily be understood that they should certainly not be entirely prohibited. M. Lecorché is even persuaded that diabetic patients can only prolong their life by continuing the use of them. He has seen and can follow up many patients who, by depriving themselves of starchy foods, rapidly fell into a state of prostration, which only left them when they freed themselves from the use of a too highly nitrogenous kind of nutriment.

M. Lecorché is equally far from prohibiting the use of tea, coffee, alcohol, and fatty substances. Tea, coffee, and alcohol are of great utility in the treatment of this disease, though, through a too superficial examination, they have been condemned by some physicians, especially by those who in the treatment of diabetes have only kept glycosuria in view. The employment of these substances may, it is true, raise the amount of sugar present in the urine in the twenty-four hours, according to Rosenstein, but this circumstance is only of slight importance.

The first thing to be striven for is to diminish the quantity of urea ; and from this point of view alcohol, tea, and coffee, are aliments, even medicines, of the first order. Alcohol may be given in all forms ; but, as we must avoid at any price the local disorders which it may produce, such as dyspepsia and gastric catarrh, it will be well to vary the preparations of it from time to time. For this reason the use of wine is recommended in preference to liqueurs, which contain alcohol only in a concentrated form, and sometimes excite the stomach too much. It is a remarkable fact that diabetic patients can tolerate a considerable amount of alcohol without showing any signs of intoxication. This immunity, doubtless, is connected with the continual washing out of the organs, which prevent this substance from forming a lodgment in them, and producing the lesions to which it generally gives rise.

Fat is also useful in diabetic cases ; and Dr. Rollo long since advised its employment

in the form of bacon. It may also be prescribed in the guise of cod-liver oil and butter. Without possessing the same value in diabetes as the nitrogenous elements, fat has the advantage, when first depositing itself in the tissues, of being able subsequently to retard the too rapid transformation of fatty diabetes into lean diabetes, and by this circumstance alone of putting off the advent of the cachectic period. Besides being more easily oxydisable than the feculents, it diminishes the proteic disassimilation by fixing part of the oxygen.

It is by endeavouring to combat this proteic malassimilation that we may hope to treat diabetes with advantage and utilise the medicines, which, given at random, are but of very secondary utility to the patient. It is for this reason that the muscular exercise which forms part of M. Bouchardot's treatment must be retained. By utilising the oxygen in the combustion of the hydro-carbonaceous substances, the muscular exertion necessarily slackens the protein disassimilation. It should also be prescribed with the object of keeping up the regular action of all the organs. If the patient have not reached the cachectic stage, hydrotherapy will be equally advantageous to him. The alimentary regimen should for the same reason be tonic, and easily assimilated on the plan of Dr. Rollo's system of diet, perfected by the later discoveries of science ; that is to say, it should comprise all kinds of nitrogenous substances in forms best suited to the patient's palate. The medicinal treatment should consist in the employment of drugs, whose action is specially marked by a lessening of the quantity of urea formed. For this purpose, the use of opium, valerian, arsenic, and doubtless bromide of potassium, is to be recommended. Opium diminishes the amount of urea, and therefore is the special remedy for diabetes ; but we must guard against excess in its use. Valerian has the same action, but is less powerful ; arsenic and bromide of potassium are still on their trial. Regarding the alkalies, which have always been recommended for diabetes, the author thus expresses himself. 'We believe, in confirmation of M. Bernard's experiments, that the alkalies in small doses augment the secretion of the gastric juice, and by so facilitating digestion, re-establish the equilibrium in an already much shaken organism. This is the actual result obtained when diabetic patients are placed on a course of alkaline artificial or natural medication ; and if in our opinion they are of no use against the diabetes, which they may aggravate, we think they are very useful to the patient in certain circumstances. All writers are unanimous in recording these successful results. The patient scarcely arrives at one of the thermal stages indicated, before digestion and sleep are restored. The urine is modified only at a subsequent period. It must, however, be borne in mind that, in order to obtain these results, we must not overdo the treatment ; and on the other hand, we must not submit to it patients who have not as yet reached the last stage of their disease. By not taking these indications into consideration, we run the risk in both cases, of bringing on the anticipated appearance of that cachectic condition which is the precursor of serious and varied complications. It is likewise in these conditions we meet with those nervous, comatose, and apoplectic seizures which often put an end to the existence of the patient.'

ABSTRACT OF A CLINICAL LECTURE ON
METEORISM. BY THE LATE PROFESSOR
OPPOLZER, OF VIENNA.*

The meteorism, which usually appears in the train of many diseases, in themselves severe, such as enteric and typhus fevers, dysentery, peritonitis, puerperal affections, &c., is in by far the greater number of cases, if it attain a high degree, a dangerous and generally unfavourable symptom, which often gives the physician cause for deep reflexion as to the manner in which he is to remove, or at least subdue as far as possible, so grave a complication of the original disease.

This symptom, appearing in the sequel and course of the diseases above mentioned, which is commonly designated by the title 'meteorism,' depends, as has long been generally known, on the distension of the intestines by the accumulation of gases in them.

If, then, this collection of gases in the intestines, and the consequent distension of the latter, become very great, it will be readily understood that such a process cannot go on without an essential influence on the functions of important organs; and also that the continuance of the symptom referred to, must of necessity interfere with and check the most important functions of these organs.

It is only too clear, and requires no elaborate explanation, that the diaphragm, subjected to the pressure which the gases accumulated in the intestines exert in all directions, is pushed more or less upwards from its normal position. This pressure, to which the diaphragm is subjected, is transferred in a manner readily understood to the lungs and also to the heart. In consequence of this pressure on the lungs, these organs are compressed, especially in the lower lobes, but also in the upper. The necessary result is, that in these parts the percussion-sound is dull, and that no breath-sound, or only a weak bronchial one, is present. It is self-evident, that the breathing remains the same if the meteorism be stationary; but that, on the other hand, if it undergo decrease or increase, the phenomena of percussion and oscillation manifest corresponding changes.

If the lower lobes of the lungs have become contracted in consequence of the pressure on them and have been rendered bloodless by the compression, it occurs as a further result that the circulation in this part must be impeded in a greater or lesser degree according to the strength of the pressure, and may be even entirely arrested. In this way, it is evident that no more blood can enter the lower lobes. As a necessary further result, the upper lobes become overfilled with blood, and hyperæmia is developed in them; this produces greater or less dyspnoea, which may attain so high a degree and so dangerous a character as to lead to pulmonary oedema and death. The symptoms of asphyxia, which may be caused by meteorism, become aggravated from day to day, especially in the course of puerperal affections which are accompanied by meteorism.

The impediment to respiration and the consequent dyspnoea may in some cases reach so high a degree, that the patients die asphyxiated.

This arrest of the circulation of the blood, by which the life of the patient may be placed in such danger, naturally extends still further, especially to

the right side of the heart; the countenance assumes a blue colour, cyanosis is developed, and the patient complains more or less of a sense of pressure.

It is evident from this brief exposition, that meteorism may become very dangerous in certain cases of disease; nay, that it may often become the immediate cause of death; and that it is in general deserving of special attention as a very unfavourable symptom.

At the same time it must be especially pointed out that—as has been established by numerous observations—the degree of meteorism bears a proportion to the greater or less gravity of the disease; in the milder point of disease it is developed in a slight degree only, while in severe cases it generally reaches a high degree of development.

With regard to the causes which give rise to meteorism, we must, in order to give as clear an idea as is possible in the present state of knowledge, first of all take a close view of the prevailing ideas regarding its occurrence in individual diseases, since only by doing this we are enabled to offer an explanation of the manner in which meteorism is developed in individual diseases, and to find out what circumstances give rise to its occurrence.

If we examine this subject, we find that there are some cases of meteorism in which a clear idea as to its cause may be arrived at, while in other cases this is quite impossible.

It is very easy to gain a clear notion of the circumstances which give rise to it in acute intestinal catarrh. It is here to be especially remarked, that the development of gases in the intestinal canal is not to be treated as a symptom or a consequence of the intestinal disease present, so long as the acute intestinal catarrh is still in that stage which is attended with increased transudation and peristaltic action. The development of gases must here be explained as being dependent upon just the same causes which, as may be often observed, in most cases give rise to the catarrh; especially the passage of undigested and decomposing substances from the stomach into the intestines.

It is also a well-known fact, that the mucus, which is formed in the intestinal canal in cases of chronic catarrh, acts in the manner of a ferment on the contents of the intestines, and thus causes them to undergo an abnormal decomposition, in consequence of which large quantities of gases are set free, leading to distension of the bowels and other troublesome symptoms.

The matter is, however, far more difficult when we attempt to discover the cause of meteorism during peritonitis; and it is no easier to explain the meteorism which occurs as a sequela of this disease. Hitherto it has been assumed that the occurrence of meteorism in such cases is due to an increased formation of gases; but this assumption is quite improbable, since indeed, no cause can be discovered which should lead to a more rapid decomposition of the contents of the intestinal canal. The assumption also, that in the course of peritonitis gas is exhaled from the intestinal wall, is devoid of any valid foundation. It appears probable that in such cases the meteorism is to be attributed in a small degree to the expansion of the gases, favoured by the relaxation of the intestinal walls, but in a higher degree to the impediment to their escape arising from the paralysis of the intestinal muscles.

If we now pass on to the diseases, such as typhus, in which meteorism is a symptom of ordinarily con-

* *Allgemeine Wiener Medizin. Zeitung*, Jan. 13, 1874.

stant occurrence, we find nothing whatever that can throw light on its etiology. The most different views have been entertained and disseminated on this subject, without having had their correctness tested by rigorous observation. And we must say plainly, that complete darkness still prevails with regard to the meteorism now under consideration; and that the explanation of the causes which produce and favour its development must be considered as a problem to be solved by science in the distant future.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

DURANTE ON THE TERMINATIONS OF THE NERVES IN THE CORNEA.—Dr. Durante, in describing the results of researches on the nerves of the cornea made by him in the anatomical laboratory in Rome (*Rivista di Medicina, di Chirurg. e di Terap.*, and *Gazz. Clinica di Palermo*, August and September), states that, by soaking the cornea of batrachians, rabbits, and dogs, in solution of chloride of gold, and keeping them at a temperature of 88° Fahr., he was, at the end of four days, enabled to see a very distinct network of nerves. When a combination of nitrate of silver and chloride of gold is used, the intercellular substance is sometimes coloured; not the fibre, which appears like a vein or capillary charged with nitrate of silver.

In frogs, the nervous trunks, from six to fifteen in number, pass into the cornea at the level of the internal elastic coat, lose their medullary sheath, and subdivide into numerous fibres, which become interlaced, and form a plexus in the interior layers of the cornea. This plexus gives origin to many other fibres, which spread out in the anterior layers of the cornea, and give off branches at a right angle. These branches in their turn subdivide in the same way, forming a network of fibres through the whole thickness of the cornea. The axis-cylinders become separated from the primitive fibres, and pass in a straight line to the cylindrical epithelium, among the layers of which they follow a winding course as far as the last layer but one, where they form an irregular network, which is best seen in sections made parallel to the anterior surface of the cornea.

The arrangement of the nerves in the cornea of the rabbit differs from that in the frog, both in direction and in mode of distribution. The nerves, sixteen to twenty in number, penetrate the cornea towards the outer part, and form a plexus. The fibrils which penetrate the epithelium proceed from the fibres which pass obliquely outwards from the plexus. Beneath the epithelium the fibres are divided into tufts and fibrils, which penetrate the epithelium, some directly, others after a short passage, and form in the penultimate layer a very fine fibrillar network, with narrow meshes. Some of the fibrils form loops in the deep epithelial layers.

In the dog, the nerve-trunks entering the cornea are smaller but more numerous than in the rabbit, and are distributed nearly in the same manner. Some of the fibres pass directly to the under surface of the epithelium, where they divide into numerous primitive fibrils, which run parallel to the anterior surface of the cornea. From these, other finer fibres are given off, which, having reached the last

layer but one of the epithelium, form the network which has been already described.

Dr. Durante did not find nerve-cells or corpuscles among the fibres, nor any termination of the nerves in cells.

A. HENRY, M.D.

BUSCH ON THE ACTION OF STRYCHNIA ON SENSORY NERVES.—Busch (*Berliner Klinische Wochenschrift*, no. 37) has observed that sensibility is so much altered in frogs poisoned by strychnia that one of the animal's toes, or the central end of the divided sciatic nerve, may be crushed or burnt without causing any reflex action. Tetanic spasms occur whenever the nerve is pulled or irritated by electricity, or whenever the animal's body receives a jar.

SCHLESINGER ON VASO-MOTOR AND UTERINE NERVE-CENTRES.—In a paper read by Schlesinger on this subject before the Medical Society of Vienna, October 17, 1873 (*Allgemeine Wiener Medizinische Zeitung*, nos. 42 and 43), he states that the experiments of Ludwig, Thiry, and others have shown that the nervous motor centre, by which the blood-vessels are kept in a state of partial contraction or tone, is situated in the medulla oblongata. When the spinal cord is cut across below the medulla at the level of the axis, and the vaso-motor centre thus separated from the blood-vessels, they relax and the blood-pressure falls. A venous condition of the blood irritates the vaso-motor centre and raises the blood-pressure when the cord is intact, but it has little effect when the cord is cut. The reflex centre of the vaso-motor nerves, through which irritation of a sensory nerve causes the vessels to contract, is usually supposed to be also in the medulla. The uterus was shown by Oser and the author to possess a nervous centre, closely analogous to that of the blood-vessels. This centre, through which reflex contraction of the uterus can be induced, also is above the atlas. It is irritated, like the vaso-motor centre, by venous blood, and thus causes the uterus to contract (*Centralblatt*, no. 52, 1871). Meyer found that strychnia stimulates the vaso-motor centre, and causes contraction of the blood-vessels and rise in blood-pressure. In his experiments this contraction and rise of pressure did not occur at all, or only to a slight extent, when the spinal cord was divided near the occiput.

The author finds that strychnia irritates the motor centre of the uterus and causes it to contract. On injecting strychnia into the blood of rabbits, the uterus becomes very pale, contracts tetanically, and assumes a cylindrical shape. Its horns become bent and finally rolled up in a knot. The contraction lasts from ten to sixty seconds, and then the uterus becomes redder than before the contraction, and is flaccid, though still rolled together. In a few seconds fresh contractions occur, which sometimes affect one horn, sometimes another, and sometimes the whole uterus. In an uninjured animal to which no strychnia has been given, stoppage of the respiration or irritation of the central end of a spinal nerve causes vigorous contractions of the uterus, but these are never so continuous and repeated as those caused by the injection of strychnia.

Although the chief part of the motor centre for the uterus lies above the atlas, it does not do so altogether, but extends some way down the spinal cord. This is shown by the fact that irritation of the sciatic nerve will cause reflex contraction of the uterus after the spinal cord has been divided above the atlas. When the cord is intact, irritation of the sciatic, crural, or median nerves, or brachial plexus, will cause reflex con-

traction of the uterus. When the cord is divided at the atlas, the effect of irritation of the median nerve is completely destroyed, that of the crural nerve only partially, while that of the sciatic is sometimes destroyed on one side, and sometimes not at all. If strychnia be now injected into the animal, irritation of the median nerve will again cause contraction of the uterus. This shows that reflex uterine centres are present in the cord, and that the median nerve is connected with them, although their presence could not be perceived till it was rendered apparent by strychnia. Conclusions regarding the localisation and limitation of nerve-centres based on the non-appearance of an effect after division of the cord are untenable.

Strychnia injected into an animal whose spinal cord is intact, causes the blood-pressure to rise, at the same time that the uterus contracts. When the uterus relaxes, the blood-pressure sinks. The effects on the blood-pressure and the uterus do not always coincide to a second, but are so closely connected that they seem to be results of a common cause. Contrary to Meyer's observations, the author finds that strychnia sometimes raises the blood-pressure after division of the spinal cord, even more both relatively and absolutely than when the cord is intact. The rise in pressure is sometimes slight and is often absent altogether. The rise in pressure can only be caused by strychnia acting (*a*) directly on the vessels, or (*b*) on nerve-centres in the cord below the atlas. When the respiration is obstructed after division of the cord and injection of strychnia, the blood-pressure either rises very much or oscillates considerably. The blood-pressure can also be raised considerably by irritation of a sensory nerve. It is improbable that the rise in pressure or oscillation is due to the action of strychnia or venous blood on the vessels; for the rise is not always present, and it seems unlikely that the vessels could act in concert so as to produce the oscillations under the influence of a nerve-centre. The occurrence of contraction of the vessels after irritation of a sensory nerve also points to the presence of a vaso-motor centre. The analogy between the vaso-motor and uterine centres and the fact, demonstrated by the author, that the latter extends below the medulla, render it in the highest degree probable that the vaso-motor centre extends from the medulla into the spinal cord; that its function becomes imperceptible, and the tone of the vessels disappears when the medulla is separated from the cord; and that this function is again rendered temporarily evident by strychnia. It is not certain whether the centres situated in the cord influence the vessels in the normal condition or not; but their apparent want of action on the vessels after section of the cord is no argument against it.

T. LAUDER BRUNTON, M.D.

SCHERSCHESKY ON THE INNERVATION OF THE UTERUS.—Scherschewsky, under Cyon's direction, has arrived at the following results (*Pflüger's Archiv*, vol. viii.). 1. The uterine plexus contains the most important, if not the only motor nerves, which can produce actual movement of the uterus, on stimulation of their peripheral ends (stimulation of the central ends produces only violent vomiting). 2. Stimulation of the central ends of the first two sacral nerves produces reflex violent uterine movements, which disappear after previous section of the uterine plexus (stimulation of the peripheral ends produce only violent contraction of the urinary

bladder and rectum). Stimulation of the bronchial, crural, median, sciatic, &c., nerves, does not produce peristaltic movements of the uterus, but only a slight rigidity and paleness of the organ. 4. The consequences of stimulation of these nerves disappears when the aorta is previously tied. Stimulation of the central ends of the sacral nerves is still accompanied by peristaltic movements of the uterus, after ligation of the aorta.

CYON ON THE INFLUENCE OF THE POSTERIOR NERVE-ROOTS ON THE SENSIBILITY OF THE ANTERIOR.—Cyon (*Pflüger's Archiv*, vol. viii.), in opposition to the negative results of G. Heidenhain, cites the following experiment from Steinmann's paper, as demonstrating Brondgeest's tonus. The gastrocnemius of a frog is weighted with twenty or thirty grammes, and the muscle is allowed, while at rest, to write upon a rotating cylinder. The posterior roots are then cut carefully with sharp scissors, and the muscle is allowed to write its length further. The weighted muscle increases in length in a marked degree, either immediately or in the course of a minute.

TARACHANOFF ON THE INFLUENCE OF CHANGES OF TEMPERATURE ON THE CENTRAL ENDS OF THE CARDIAC NERVES.—Tarachanoff (*Pflüger's Archiv*, vol. viii.) finds, in opposition to Fick, who says that the central ends of the cardiac-nerves are not influenced by changes of temperature, that, in passing defibrinated blood under normal pressure through the vessels of the brain, after ligation of the carotid and vertebral arteries, and of the veins, sudden increase of temperature of about 18° Fahr. acts as a stimulant in the most powerful manner, on the central ends of the vagus, and quite in accordance with the action on the peripheral ends of this nerve.

WILLIAM STIRLING, D.Sc., M.B.

PATHOLOGY.

TROISIER ON TWO CASES OF SCLEROSIS OF THE SPINAL CORD.—M. Ém. Troisier relates two cases of spinal sclerosis (*Archives de Physiologie*, Nov.). The first patient, under the care of M. Vulpian, was of a scrofulous diathesis, and had suffered from glandular enlargements, eruptions on the skin, and various strumous complaints. There was no history of syphilis. About two months before he came under notice, he suffered from shooting pains in the lumbar region. The pain was worse at night, and interfered with his sleep. It, however, did not prevent him from carrying on his business, which was that of a worker in a copper-mill. About the same time he suffered from dysuria, constipation, and pains in the lower limbs. These pains became worse, and in about a month he found that his limbs were growing weak, and ultimately he completely lost the use of them. The urine flowed away when the bladder was full. A large sore made its appearance over the sacrum. There was no curving or weakness of either the spine itself or of the upper limbs. There was no pain on percussion of the spine. On his coming under observation, the lower limbs were found to have lost all power of voluntary movement; there was some slight reflex action of the muscles when the sole of the foot was tickled. The muscles were not atrophied, they contracted well under the influence of inductive

currents. The sensibility of the skin of the lower limbs, though impaired and altered, was not lost. The upper limbs and the face seemed free from any functional disturbance. The patient felt no desire to pass urine or for the bowels to act. He lived about one month after he came under observation.

At the necropsy, with the exception of some slight congestion of the superficial vessels, the brain was found to be healthy. The vertebræ and the dura mater all along the spinal canal were healthy, nor was there any tumour found there. The arachnoid and the pia mater did not present any signs either of congestion or inflammation. The sole lesion to be found was on the posterior surface of the spinal cord. Here there was a small patch of sclerosis, which was situated about an inch above the lumbar enlargement. This patch was composed of two small spots placed one above the other. The inferior, which was the larger, extended both to the right and to the left of the median fissure; it however did not pass beyond the limits of the posterior columns. On the left side it sent out a small prolongation, which was confined to the posterior column of the cord. The superior spot passed a little to the right of the median fissure. These two spots, although distinct, yet were very closely connected with each other, and together formed an irregularly shaped patch a little short of half an inch in length. They were greyish-red in colour, slightly depressed, and offering less resistance to pressure than the normal tissue. The nerve-roots presented no alteration at this place.

On cutting into the cord, after it had been hardened in chromic acid, the extent of the sclerosis was found to be as follows. In the upper part, it occupied a small angle of the cortex of the posterior columns at their internal part. Towards the middle of the upper spot, it presented the appearance of a very narrow crescent, one angle of which reached the left posterior lateral fissure, and the other extended itself over the most internal part of the right posterior column. Towards the lowest part of this spot, the sclerosis was only on the left side. In the interval which separated one spot from the other was found only a small round spot of sclerosis, which occupied the left posterior column, and which was separated from the surface of the cord by healthy tissue; this spot was nearer to the posterior horn than to the median fissure. Soon it increased in size, and gradually extended itself from the posterior horn to the edge of the posterior column in the form of a triangle. On cutting lower down the cord, the same disposition of parts was found, but the triangle was not so deep, and was somewhat separated from the grey matter. Lower still, the sclerosis was confined to the cortex of the posterior column. It gradually spread thence to the cortex of the right posterior column, and finally disappeared. On examining these spots with a higher power, after the sections had been rendered transparent, the following appearances were found:—1. A central part formed by vertical and transverse fibres intersecting each other, with some occasional appearance of axis-cylinders scattered here and there among the fibres; 2. A zone of transition, in which the neuroglia was much thickened and the nerve-tubes more or less atrophied, but all preserving their axis-cylinders; the vessels were considerably developed in this and in the preceding portion; 3. An outside zone, which presented the same alterations as the preceding, but to a less advanced degree; on the borders of this zone there was only a simple increase of the nuclei of the neuro-

glia. The grey matter, where the sclerosis approached it, was not altered.

The pathological appearances above described lead one to imagine that this was a case of that disease of the spinal cord known under the name of '*sclérose en plaques disséminées*'; the progress and the symptoms of the disease in this case, however, render this conclusion doubtful.

There was not any reason to think that the disease was of a syphilitic nature. The great question which arises is, how is it that a disease, the seat of which was so limited, was able to produce all the symptoms of spinal compression? Two explanations present themselves: one is that the sclerosis exerted a kind of transverse retraction on the cord, and so simulated compression; and the other is that the symptoms were produced by vascular derangements ('*troubles vasculaires*').

The next case occurred in a female patient who was under the care of M. Charcot. She was forty years of age. She had been healthy all her previous life up to the age of thirty, when she had a bad confinement, and was attacked by hallucinations and insomnia, which were both persistent for some time. These symptoms, however, after six months, somewhat improved, only appearing at the menstrual period. About this time she felt a pain in the spine, at the lower part of the dorsal region, and had feebleness and loss of sensation in the lower limbs. On awaking one morning, she found herself completely paralysed on the left side. From this she gradually recovered, and the only trace of the attack for several years was a weakness of the left leg. For fifteen months before coming under observation, she had been subject to a sharp pain like that of a burn at the level of the sacro-lumbar articulation, which pain seemed to spread all down the right lower limb. At times that limb was jerked spasmodically. From December, 1866, she had been subject to indefinite nervous attacks, which were worse after any emotional excitement. On one occasion, after speaking for some time, she was seized with faintness, and was obliged to lie down; she could move on the bed, but lost both the power of speech and of swallowing; she did not lose consciousness. This attack lasted about a quarter of an hour, when she was seized with a violent rigor, followed by heat of the surface: the attack terminated with some slight trembling of the upper limbs. She had a similar attack almost daily till February, 1867, and then again for three months in the course of the year 1868.

In March, 1868, the following was her condition. There was pain on pressure over the dorsal vertebræ. The bowels were constipated; there was no incontinence of urine. There was decided loss of power in the left lower limb, which was much more feeble than the right. The upper limbs seemed in a healthy condition, as also did the organs of sense. She had a good appetite; no cough; the heart-sounds were clear and the menstruation was regular.

On Jan. 6, 1869, there was no loss of sensation in either of the lower limbs. On the left side tickling, pricking, pinching, heat and cold were all recognised as such, but on the right they all gave rise to a sense of pain. The reflex movements of the limbs, on application of an irritant, were more marked on the left side than on the right. The patient complained of constant pain at the sacro-lumbar articulation, and of painful feelings and startings ('*impatiences*') in the right leg and arm.

On March 7, 1870, for the last three months the

patient had been better. She could walk with the aid of crutches, and go upstairs. The left limb was still slightly weaker than the right, and the left foot was a little contorted, but the sensibility of the surface remained good. The moving power of the right limb was good, but was accompanied by pain at the sacro-lumbar articulation; the sensibility was not so good on this side as on the left. The reflex movements were nearly equal on both sides. Pressure on the lower lumbar vertebrae produced pain.

The patient died of phthisis brought on by the privations undergone during the siege of Paris, on June 17, 1871. The left lower limb had become contracted during the interval between the last note of the case and the patient's death. On opening the spinal canal, the arachnoid was found thickened, particularly behind, where were developed numerous fibrous patches; the nerve-roots were very vascular. Towards the middle of the dorsal region of the cord, the left half presented a greyish tint and all the characters of sclerosis for some centimètres in height. It was very difficult in the fresh state to determine the extent of this lesion; but after hardening the cord in chromic acid, it was found that the sclerosed part was about three inches in length. The entire left side of the cord seemed atrophied when compared with the right side. In a section of the cord made between the sixth and seventh dorsal nerves, the left half was about the $\frac{1}{30}$ th part of an inch smaller than the right side. The sclerosis occupied the antero-lateral column on the left side in its entire extent, with the exception of a very small portion of the posterior part of the lateral column; the grey substance on this side was also invaded, and only the vascular columns of Clarke and a portion of the commissure situated behind the central canal could be distinguished. The posterior median fissure had deviated towards the left side and formed a curve, with the concavity towards the right. The left posterior column was atrophied, but only partially affected by the sclerosis. It had the appearance of being retracted. There was a band of sclerosis passing from the principal centre of disease, which crossed it obliquely from before backwards, joined the median fissure about the middle, and followed it to the surface of the cord.

In a section made about half an inch above the former, a similar appearance was found, but less advanced. The disease occupied nearly the entire antero-lateral column, distorting the grey substance, which, however, remained distinct. The posterior column was also slightly affected.

In a section made an inch above the last, the sclerosis was only fibrillar in the cortex of the left antero-lateral column; in the rest of the cord it was more diffuse. At about two inches above the first section the lesion presented nearly similar appearances. Further up still, it gradually faded out. Below, it disappeared at about the first lumbar pair of nerves. The disease seemed to disappear above in the posterior columns, below in the lateral. This fact would seem to indicate the course of the disease; the paralytic weakness of the left inferior limb which showed itself early in the illness, and no doubt took its origin in the original centre of the myelitis, finished in a permanent contraction of the limb, which condition, it is well known at the present time, is associated with sclerosis of the lateral columns. It is laid down as a rule that, when the lesion affects an entire lateral column of the cord, whatever may be its vertical extent, it produces a paralysis of the muscles of the

side corresponding to that attacked, and a paralysis of sensibility on the other side. The above case would seem to bear this out. The perversion of sensibility noticed in the right limb of this patient is what M. Charcot proposes to call *dysæsthésie*, and is specially noticeable in cases of myelitis caused by compression.

W. KESTEVEN, Jun.

VENUTI ON A PECULIAR RETROGRADE CHANGE IN EPITHELIOMA.—Dr. Venuti describes (*Gazzetta Clinica dello Spedale Civico di Palermo*, July, 1873) the appearances presented on examination of a specimen of epithelioma of the penis. He has not, he says, been able to find an account of similar change in the works of Rindfleisch, Cornil and Ranvier, or Thiersch.

The growth involved the entire glans, and had become reduced by destructive changes to the size of a small nut. Its surface was divided here and there by fissures of greater or less depth, in some of which the opposed surfaces had become glued together, so as to form *culs-de-sac*. The surface was in other respects smooth, not having a cauliflower appearance. The urethra opened in its centre, in the midst of a large ulceration.

The specimen having been hardened in alcohol for some days, sections were made, both vertically and parallel to the surface. The stroma was rich in embryonic cells. The epithelial cells were all dentated, with single nuclei, the latter being in nearly all cases round. There was an extreme rarity of 'concentric globes.' The most remarkable appearance was a process of involution or destruction of the epithelial cells, commencing towards the centre of the lobules, and attaining its maximum at their periphery. The cells were flattened and their nuclei enlarged; and this enlargement of the nuclei became greater, while cell-walls entirely or partly disappeared. This generally occurred in adjoining cells, so that the nuclei, coming into contact with each other, formed a granular mass, generally enclosed in hollow or spherical spaces, bounded by walls. Sometimes a space contained a single enlarged nucleus; sometimes there were larger or smaller isolated groups of granules not enclosed in walled cavities. The presence of the walled cavities containing granular detritus was, however, the main feature of the case. The walls presented irregular longitudinal striæ, and their thickness was in proportion to the size of the space enclosed. In a more advanced stage, the walls uniting the spaces disappeared, and the granular masses became fused together.

The application of solution of iodine produced no change of colour. Caustic potash dissolved both the walls of the containing cavities and the granules. Neither ether nor chloroform had any solvent effect.

A. HENRY, M.D.

GUÉNIOT ON AN ANOMALY OF THE ŒSOPHAGUS CAUSING STARVATION.—M. Guéniot communicated to the *Société de Chirurgie* (Dec. 10), the case of an infant born with what was diagnosed, and at the necropsy proved to be, an anomaly of the œsophagus, which presented an interruption of continuity. The upper end terminated in a *cul-de-sac*, at 4 centimètres below the first tracheal ring, the lower end springing from the stomach came up to the level of the bifurcation of the trachea. The child lived seven days without taking food, which is interesting from a medico-legal point of view. M. Guéniot observed that, if cases of the kind recurred, the question of nutrition by gastric fistula might be entertained.

DEBOVE ON THE PATHOLOGICAL HISTOLOGY OF 'SCLÉROSE EN PLAQUES.'—Dr. Debove (*Archives de Physiologie*) says that it has been long admitted that there are two distinct parts in the nervous centres, the one nervous and the other connective, the latter serving for the support of the former. Our knowledge of the connective tissue is still incomplete, notwithstanding the labours of Deiters, Jastrowitz, Boll, and Golgi. According to these authors, sclerosis of the nerve-centres results from an excess of neuroglia, and ought, therefore, to be composed of *cellules chevelues* (*cellules araignées* of some authors), from which are given off minute hair-like processes.

The separation of the sclerosed parts is equally difficult in a fresh condition, as after maceration in weak solutions of chromic acid. In some sections of nerve-tissue, stained and examined in Canada balsam, the form, limits, and exact situation in the alteration may be easily recognised. There can be seen in this tissue only bundles of fibrils, collected together and pressing on the nerve-tubes, and nuclei scattered about among these bundles.

Interstitial injections have afforded remarkable results to M. Ranvier, when he has applied them to the examination of the connective tissue. This method, however, has not afforded M. Debove any result, at all events as far as the normal neuroglia is concerned. The injection broke up the elements of the tissue, but did not separate them.

M. Debove attempted to apply the method to patches of sclerosis of the spinal cord in a case of cerebro-spinal *sclérose en plaques*. The specimen was obtained from the body of a patient who had been under the care of M. Charcot, at the Salpêtrière. The disconnection of the elements appears to have taken place, but the injection escaped from the surfaces of the section. A more successful attempt was made on some patches of sclerosis, discovered under the ependyma of the lateral ventricles (*plaques ventriculaires*). The proceeding employed was as follows. The syringe being full of a lukewarm solution of gelatine, the cannula was introduced under the ependyma to about the centre of the patch of sclerosis; the fluid was then injected, and a bulla was formed; this bulla was allowed to harden, and then cut into small pieces. These were coloured with picrocarminate of ammonia, some before, some after the breaking up of the cut pieces. It was then perceived that the sclerosed patch was formed of two elementary parts, viz., of fibres and cells, completely dissociated. The fibres were fine, long, independent of the cells, and not united into bundles, but of such a kind that if they really were naturally in bundles, they were so feebly united as to be easily separated by the injection. In the interval between these fibres were seen some flat cells, with elongated nuclei, having a fine transparent protoplasm, with an irregular outline; they did not present that appearance of processes which would justify one in calling them spider-cells (*cellules araignées*). They exactly reproduced the characters and the appearances of the cells of the ordinary connective tissue. The structure of the subependymic patches of sclerosis is therefore like that of the subcutaneous connective tissue. The cells are exactly the same; the principal difference appears to be in the disposition of the fibres, which are here isolated, or very slightly connected to one another, contrary to what is the case in the ordinary connective tissue. M. Debove does not affirm that in the sclerosis, scattered in multiple patches throughout the nervous arches, all the patches pre-

sent the same composition. M. Pierret, in the same case of *sclérose en plaques*, states that he obtained, by the dissociation of a patch situated deep in the cerebral hemisphere, some cells approaching by their characters those cells called the cells of Deiters, or cells with processes.

SURGERY.

SEWELL ON THE PASSAGE OF HAIRS FROM THE BLADDER.—Dr. Sewell, in the *Canada Medical and Surgical Journal* for October, 1873, describes the case of a female child who passed hairs with her urine and drew long hairs from the mouth. She was three years and nine months old. She had been under observation from May to August, 1873, in the Female Orphan Asylum at Quebec. The little orphan was very backward in speaking, of feeble intellect, and of dirty habits, passing everything on the floor in a standing posture. She suffered from frequent micturition, and urinated frequently with more or less pain. Each discharge of urine was found to contain a number of hairs varying from one to seven inches in length. In August they were estimated at one dozen daily. Each hair exhibited, under the microscope, a well-defined bulb, and all the characteristics of ordinary hair. Generally the hairs were fine and of a light colour, occasionally darker and coarser. There was no calcareous matter about them. The urine was of specific gravity 1018, and free from mucus, pus, or blood.

Dr. Sewell says that his case, though an uncommon one, is so far not unique. There is, however, another feature which, added to the above facts, make it really, so far as he can discover, perfectly unique. The child is constantly drawing similar hairs, from eight to ten inches in length, from her mouth. These are frequently coated with bloody mucus. He has never seen her draw any from her mouth, but some of the lady visitors have; and he implicitly relies on the report of the matron.

[The author is quite right in stating that his case is not unique in passing hairs in the urine, as there are now several cases on record, five females and three males. 1. Hildanus, in a letter to Horstius (*Horstii Opera Medica*) relates the case of a woman aged 60, who was under his care from 1616 to 1620, and appears to have been the subject of a dermoid cyst. 2. In the *Philosophical Transactions*, page 700, there is an abstract of a case of Dr. J. Wallace's. A gentleman passed long hairs during his life-time, and after death a soft concretion was found in the bladder. 3. In 1733 Mr. Powell communicated to Sir Hans Sloane the particulars of a widow lady, who passed hairy crustaceous substances in her urine, which was whitish like whey. 4. In reply Sir Hans Sloane gave an account of a brewer who suffered from the passage of long hairs matted and woven together, with little or no calculous matter attached to them. 5. Dr. W. Henry, in the 10th vol. of the

Medico-Chirurgical Transactions, 1819, has described the case of a middle-aged man who passed hairs varying in length from one-tenth of an inch to one inch. He conjectured that the hairs had been attached to the bladder or some of the urinary passages; but there was no positive evidence of this. Dr. Wollaston examined some of the hairs from Dr. Henry's case, and found that they did not differ chemically from ordinary hairs, but they differed mechanically in not possessing the roughness in one direction on the surface, upon which the felting property of every kind of common hair depends. 6. Delpech, in his *Chirurgie Clinique*, 1828, narrates the case of a young married woman, twenty-seven years of age. She passed hairs, and he removed by the urethra masses of hair, scalp, bone and teeth. He believed it to have been the result of a conception, the cyst to have been situated in the 'ad uterum' and to have opened into the bladder. It was obviously a dermoid cyst. 7. In the *Lancet* of November 10th, 1860, Mr. Hall has detailed the case of a married woman, aged 60, who suffered from the passage of hairs, and from a concretion which he extracted. Her case was probably one of dermoid cyst, though Mr. Hall conjectured that the hairs had grown from the walls of the bladder. 8. Dr. Fuller has described an interesting case in the *Transactions of the Pathological Society* for 1870. A married lady, aged fifty, suffered for several years before a cure was effected. It was determined, with reason, that a dermoid cyst had been the cause of her troubles.

[With regard to the fact of the hairs drawn out of the mouth, Dr. Sewell does not state whether he explored the mouth or made any physical examination of the chest, or whether the child was the subject of cough. A case of dermoid cyst in the lung, described by Dr. Cloëtta (Zurich) is of interest as bearing on this part of Dr. Sewell's case; and, therefore, I give an abstract of it from Schmidt's *Fahrbücher*, vol. 110. A female, aged twenty, was the subject of pulmonary tuberculosis, and expectorated large quantities of hairs. The lower lobe of the left lung was found after death to present a cyst in which hairs, fatty matter, cartilage, and bone were imbedded. This cyst opened into a large cavity on the lung, which was occupied by dead hairs, epithelium, and fat.—*Rep.*]

JOHN CROFT.

MANSON ON LYMPH-SCROTUM.—Dr. Manson (*Cus-toms Medical Reports—China*, Oct. 1872 to March, 1873) describes, under the name of 'lymph-scrotum,' a peculiar disease of the scrotum, of which three cases have been described in a previous number of the same reports. Five cases are referred to here, and another had been in hospital, but no notes were taken. The notes of these two cases are given *in extenso*, translated from the Chinese clerks' notes, and at the end the leading facts of the whole eight cases are tabulated. The patients were men practising various kinds of labour, and of ages varying from nineteen to seventy-two. Six of them were known to have been liable to ague, and in the other two cases the matter was not inquired into; the duration of the disease had in no case exceeded two years. The characteristic of the disease was the formation of vesicles in the skin of the scrotum (only two in one case, in another innumerable), from which exuded an albuminous fluid, variously described as 'clear and straw-coloured,' or 'milky,' and sometimes blood-tinged, spontaneously coagulable, and containing, under the microscope, 'two kinds of cor-

puscles, in most respects like those of the blood. The two kinds appeared to be in about equal proportions. Those similar to the red corpuscles differed from those of the blood in not exhibiting any disposition to accumulate in rouleaux, but rolled across the field one independent of the other. Thus they exhibited many different shapes according as the surface or the edge of the disc was presented to the eye.' A sketch of the two kinds of corpuscles is given.

In all the cases noted there was enlargement without suppuration of the inguinal glands. In six cases there had been abscess of the scrotum, which, however, was absent in two of the cases, though in one of these latter there had been swelled testicle. The son of one of the patients suffered from elephantiasis of the leg. As far as can be judged from the description, the skin was natural except in the part where the vesicles were formed, and in the immediate neighbourhood, where it was swollen and thick.

A singular omission in the paper is that nothing is given beyond this description of the local changes. There is no mention of the effect (if any) on the general health and condition, nothing as to the etiology, nothing as to the treatment of the disease. The conclusion must be that the disease produces no effect on the general condition, and that no efficient treatment is known; yet it would have been more satisfactory to have had this clearly stated.

[Many of our readers are aware of the case related at the Clinical Society some years since, of a boy, the son of a well-known physician in London, who suffers from occasional profuse discharge of lymph from the scrotum. In this case there is hypertrophy of one lower extremity, and at times much interference with the general health. Several other cases of varicose lymphatics have been recorded, but we were not aware that the affection prevailed anywhere endemically.—*Rep.*]

T. HOLMES.

SIMONIN ON RAPID DILATATION OF THE FEMALE URETHRA.—M. Simonin, of Nancy (*Innocuité et Utilité de l'extreme Dilatation de l'Urèthre chez la Femme*, &c., Nancy, 1873), arrives at the following conclusions. Rapid dilatation of the female urethra may be effected painlessly under anæsthesia, so that the forefinger or a forceps charged with calculi, and having a total circumference of 68 to 70 millimètres (2·7 to 2·8 inches) may be passed without difficulty. This may be done without rupture of the canal, and without producing incontinence. In one case, where incontinence existed owing to the presence of a calculus in the bladder, it ceased after removal of the foreign body.

MATERIA MEDICA AND THERAPEUTICS.

BESNIER ON THE USE OF CHLORAL HYDRATE TO ARREST INCIPIENT ABORTION.—Dr. Besnier of Paris (*L'Union Médicale*, Sept. 27, 1873), has lately used chloral hydrate in a case of threatening abortion with a perfectly satisfactory result.

The patient, a young primipara, six months with child, was taken with pains in the evening of July 11, and was seen by Dr. Besnier on the evening of the ensuing day. She had manifest contractions of the uterus, accompanied by pain, recurring every ten or twelve minutes; pulse 80; child active; no cause of premature labour could be made out. Opium was first resorted to. An enema with twenty drops of laudanum produced little or no effect; a second and third, followed by ten drops by mouth, were given with like result. Chloral was then tried. A first dose by mouth being rejected, an enema with forty-five grains of chloral was administered; almost immediately all labour-pains ceased, and the patient fell into a deep sleep, which lasted three hours; a second and a third enema, each with thirty grains, each produced two hours of quiet sleep. At every awaking the contractions reappeared, weaker each time. Laudanum was then again used, in doses of twelve or fifteen drops, every two or three hours, according to the indications; and this medication was kept up during the two following days, by which time all apparent danger had subsided. No phenomena worthy of note occurred after the sedation of the uterus thus obtained. No narcotism was apparent, nor was any disturbance caused by the chloral. The foetal heart-sounds and movements showed a perfectly satisfactory condition of the child.

Dr. Martineau, having obtained similar good results in a case of abortion (*Gazette des Hôpitaux*, March 25, 1873), attributed the sedation of the uterus to a supposed 'amyosthenic action exerted by chloral upon the uterus.' Dr. Besnier, however, adopts a different interpretation. Recalling the observations of Dr. Lambert (of the Edinburgh Lying-in Hospital), who found chloral to increase the energy of the uterine contractions, rendering them shorter in duration, less frequent, and more powerful (see *Gaz. Hôp.*, Feb. 22, 1873), Dr. Besnier is struck by the apparent contradiction in the action of chloral used in similar doses in abortion and in accouchement at term, and he tries to reconcile the contradiction. He thinks that, in normal parturition, contraction of the uterus is excited by mechanical action, exerted by the distended membranes, head or presenting part, &c., and that the contractions thus instituted are partly kept up by the reflex action of the labour-pains; while in abortion, the contractions are generally produced, not by any continuous mechanical agency, but by some accidental and passing cause, as a blow, fall or fatigue, the pains being the cause which occasions continuance of the labour. Dr. Besnier, adopting the theory that chloral owes its action to chloroform which is set free in the blood, admits that when given in labour, chloral acts as an anæsthetic, which, in normal parturition, suppresses the pains, leaving the mechanical agency to act undisturbed; the contractions being less frequent, and of shorter duration, allow the uterus to recover more fully during each

interval, whence their greater energy. But in abortion, on the other hand, the anæsthetic action of chloral suppresses the pain, and with it the only cause of the uterine contractions. Thus the happy effects of the drug are explained without the necessity of invoking any paralysing effect exerted upon the muscular fibre of the uterus.

Of course, if the foetus or placenta were engaged in the os uteri, the conditions would become similar to those of normal parturition, and chloral would only be useful as an anodyne, in relieving pain, not in preventing miscarriage.

Dr. Besnier draws attention to the utility of combining the action of chloral and of opium; and he recalls in this connection the experiments of A. Bernard, and the observations of Guibert, Joujon and Labbé, on the association of chloroform and morphia, which show that the anodyne effects of both drugs are much enhanced by their combined use.

On this communication, the reporter in the *Boston Medical and Surgical Journal* remarks, that M. Besnier's observation and reflections are interesting, as they exemplify and explain the usefulness of chloral in abortion, where we would expect the drug to produce harmful effects, from our previous experience of its action in connection with labour. Dumas, Liebreich, Personne and others have shown that chloral hydrate in presence of alkali is decomposed, chloroform and formiate of the alkaline base being produced. It is quite generally admitted, as asserted by Liebreich and assumed by Dr. Besnier, that this reaction is realised in the blood; and to the chloroform, supposed to be thus disengaged conjointly with an inert formiate, the sedative effects of chloral are attributed.

Dr. Gamgee (*Pharm. Journal and Trans.*, 2nd series, vol. xi. p. 464) has shown that this reaction, which seemed to explain so plausibly the sedative action of chloral hydrate, is only realised when the chloral is treated with *caustic alkali*, and that the salts to which the blood owes its alkalinity are incapable of decomposing chloral at the temperature of the body; the alkaline phosphate of sodium fails to accomplish the production of chloroform, even at boiling heat, while with the bicarbonate of sodium chloroform is only given off after the temperature has been raised above 70° Centigrade (158° Fahr.) Dr. Gamgee, also, clearly shows that the symptoms produced by small doses of chloral are quite out of proportion to those which might be expected to result from equivalent quantities of chloroform, supposing Liebreich's theory to be correct. The physiological effects are also known to be different, chloroform often producing insensibility before sleep and annuling reflex action, while with chloral, anæsthesia is only obtained indirectly, as the result of sopor, and reflex actions are often rendered more intense instead of being diminished or suppressed. Dr. Gamgee concludes that chemical facts as well as a consideration of the physiological action of chloral and of chloroform militate against the chloroform theory.

Dr. Gubler, of Paris, has also arrived at the same conclusions, having found that the production of chloroform from chloral is only effected by caustic alkalies, and not by the alkaline salts present in the blood.

Until further demonstration, therefore, it would, perhaps, be prudent in studying the action of chloral to carefully observe its intrinsic properties, rather

than to rest satisfied that the drug owes all its properties to gradual evolution of chloroform.

PICHLER ON THE THERAPEUTICS OF GALL-STONE COLIC.—The *Allgemeine Wiener Med. Zeitung* of November 18, 1873, contains a short article on this subject, by Dr. W. Pichler, who is one of the medical men attached to the Carlsbad baths. He remarks that gall-stones are matters of daily occurrence in Carlsbad practice—at least in large practices. On this account the local doctors have a larger experience of these concretions than any other medical men. No meeting of the Carlsbad Society for Natural Sciences and Medicine occurs without the communication of cases of cholelithiasis, some of which are of great interest. Last session, gall-stones were several times exhibited, of the size of chestnuts, which had been discharged without difficulty; not indeed by the natural passages, but in some abnormal fashion, such as results from chronic inflammation of the gall-bladder, leading to perforation of the intestine, and the escape of the gall-stone by the bowels. But these cases of large gall-stones, though very interesting, are scarcely more so than those in which great numbers of these calculi are discharged. There have been cases shown where thirty gall-stones, each of the size of a large pea, were passed at one action of the bowels; whilst in one remarkable case nearly three hundred, varying in size from that of a millet-seed to that of a pea, were thus discharged. He says he might recite a large number of cases of gall-stone colic, which are highly interesting for their long duration, their severity, their complicated course, or the implication of the nervous centres. But he reserves these details, and his views as to the mechanism of their incarceration, to another occasion, wishing rather to devote a little space to the practical question of the treatment to be adopted. The severity of the pains is well known, and women often say that they are far worse than those of childbirth. On account of this severe character, and from the fact that all sorts of reflex phenomena, vomiting, severe rigors, epileptiform and other convulsions, and the like, are frequently associated, it may easily be understood that next to the application of warmth, in the form of cataplasms and baths, narcotics must play a leading part in the treatment; opiates, morphia by the mouth or rectum, and subcutaneously injected, and chloral-hydrate being all employed by turns. Success in the employment of narcotics for this object, depends very much on the skill of the prescriber—and he very seldom complains that there are too many medicines of this class. Nor is the mode of application indifferent. The result of much experience of some of the most painful cases is, that the best results are obtained from hydrate of chloral, combined with the internal or subcutaneous use of the salts of morphia. For it often happens that moderate doses of these preparations of morphia are of no use against the severity of the pains, and we may, from special reasons, be disinclined to have resort to larger and more dangerous doses. In such cases let a dose of chloral hydrate be administered, and we shall soon be gratified with the result. Trials of each separately, and of the two in combination, have convinced him of the superiority of the combination to the use of either alone. After Dr. Pichler had found this experimentally, he learned that others had made a similar discovery. For example, Nussbaum found that a patient, who had by

mistake received a subcutaneous injection of acetate of morphia before being chloroformed, slept for twelve hours after the operation, and was during this sleep insensible to all kinds of painful impressions. Claude Bernard found that chloroform narcosis lasts much longer in animals, to whom opiates have been given beforehand. Goujon and Labbé, from repeated experiments, announce that the combination of small doses of morphia with chloroform produces several hours' complete insensibility to pain, although there may be no sleep. Another French observer, Rabuteau, has made this experiment. He gave five centigrammes (= 0.77 grain) of narcenin to a dog, and then chloroformed him. After waking from the narcosis, the dog was quite insensible to pain, although he went round the room, and recognised his master. There was complete anæsthesia; he could be pinched, pricked, or have his toes trod on without any sign of feeling, and, although full grown, sensation did not return till the next day. The combination of chloral hydrate and morphia offers similar advantages to the practical physician, and Dr. Pichler recommends it most strongly in gall-stone colic, in the passage of renal calculi, and in neuralgia.

[This paper is so condensed, and so practical, that I have omitted only a word or two here and there. Many English physicians and surgeons will corroborate the author as to the advantages of combining narcotics; but it seems hardly out of place to insist upon the necessity of great caution in the use of such combinations.—*Rep.*]

W. BATHURST WOODMAN, M.D.

REVIEW.

Syphilis, its Nature and Treatment, with a Chapter on Gonorrhœa. By C. R. DRYSDALE, M.D., &c. 2nd Edition. Large 8vo, pp. 165. London: Baillière, Tindall & Co. 1873.

Dr. Drysdale's honesty of purpose throws a charm over his writings that makes criticism an invidious task. Yet it is difficult to conceive what end the author set before himself when he began to write this work on venereal disorder. His learning is great, too great for his judgment, and he thus throws upon his reader the task of criticising and weighing the evidence collected with painstaking impartiality from many sources, without the slightest attempt to estimate the value of the contradictory observations or expressions of opinions thus strung together almost at random.

One example of our author's mode of setting forth his evidence will suffice. Dr. Drysdale's favourite pursuit is the denunciation of the use of mercury for therapeutic purposes; and he recapitulates much of the testimony against its employment that was published when the prevailing opinion that all venereal diseases were syphilitic and could only be cured by mercury, gave rise to great abuse of that drug. Among other testimony he fills several pages with Groves's account of the experience of Fricke of Hamburg, when treating the venereal patients brought under his care in the hospital at Hamburg. Our author, however, makes no mention of the fact, being probably unaware of it, that Fricke, before he adopted non-mercurial treatment, employed mercury in treating all venereal affections, gonorrhœa, phimosi, soft sores, abrasions, general syphilis, &c., and naturally enough, as we know at the present day, would find a

vast improvement in his general average of success, if mercury were no longer administered indiscriminately to such cases. Many would benefit, even if a smaller number suffered by excluding mercury from their treatment. This fact renders Fricke's testimony worthless in determining whether mercury is beneficial in treating syphilis, unless his experiments were continued over a period of time greater than that necessary for the expiry of the disease, and the cases of truly constitutional syphilis were eliminated from the other simpler venereal affections. Fricke's observations occupied three years; his results were given to the world in the fourth. What became of the really syphilitic patients whose early career was passed in total abstinence from mercury, we have never heard, as Fricke, though he continued to direct the treatment of the venereal patients of the Hamburg Hospital for several years afterwards, published no more reports of his system. All we know is that, ten years later, when Groves applied to him privately, to know if he still carried on the non-mercuric treatment of venereal diseases, Fricke replied that he was more firmly than ever convinced of the advantage of withholding mercury. This is probable enough; few men like to avow themselves mistaken after solemn profession of faith; and even the most determined mercurialist of the present day would be loth to use mercury on the condition that, if used at all, it must be applied to all venereal patients, syphilitic and non-syphilitic alike; and when Groves wrote, men still believed in the common origin of gonorrhœa, soft sores, and syphilis. Under such circumstances, we can only urge Dr. Drysdale to bear in mind that, in reasoning, expressions of mere opinion go for nothing, and that the facts from which deductions are made must have sufficient detail to establish their validity before they can be accepted as trustworthy props in the edifice which the reasoner desires to erect. In a future edition, we hope the author will subject the evidence he has collected to analysis, in order that his reader may estimate fairly the opinions quoted from many observers, and accord to them severally something approaching to their true value.

Having expressed so freely our opinion of the demerits of Dr. Drysdale's book, we hasten with pleasure to acknowledge that the work is written by one who takes great pains to keep himself informed on the subject he treats, who gives his own experience with great modesty and accuracy, and whose pages may be advantageously consulted by all wishing to learn the most recent views held by practitioners in this department of medicine.

Métallothérapie : Du Cuivre contre le Choléra ; Rapport officiel de M. le Dr. VERNONIS, sur l'Immunité cholérique des Ouvriers en Cuivre. Instruction pour le Traitement préservatif et curatif. Par le Dr. V. BURQ, Médecin-consultant à Vichy et à Nice.

The author of the above pamphlet asserts that he has made the discovery that workers in copper enjoy a special and almost a complete immunity from cholera. The conditions necessary for securing this immunity are stated to be that the dust of copper shall be inhaled daily and unmixed with other metals. A workman ceases to be protected if he be absent from his workshop sufficiently long to permit the elimination of the copper from his system. And a mixture of iron dust with the copper inhaled, prevents the formation of soluble and assimilable

copper salts in the stomach, upon which the protective influence is assumed to depend. The mixture of iron with copper, therefore, is declared to deprive the latter metal of its protective influence.

The statistical statements which are set forth in support of the proposition that workers in copper have an especial immunity from cholera, are unsatisfactory by reason of the absence of those details which are essential in all inquiries relating to the etiology of disease and the influence of protective and curative agents.

For the prevention and treatment of cholera, Dr. Burq recommends frequent and large doses of the oxide of copper or of the double chloride of copper and ammonium. Amongst other means of prevention and of cure, especially for the cramps of cholera, he advises the application of belts and bracelets made of copper coins, connected together by bands. Now, since we are told that the beneficial influence of copper is dependent on the formation of soluble salts in the stomach, and that the mixture of iron interferes with this essential process, we are at a loss to understand the *modus operandi* of copper coins applied to the surface of the body. The pamphlet under consideration being addressed to the public, and not exclusively to the profession, the author hints at, but shuns, the details of the sad spectacle presented in the obstinate and unreasonable opposition of his professional brethren, whose opposing arguments, he says, abound in errors, inexactitudes, and puerilities. In short, Dr. Burq has failed to convince his brethren, and he has equally failed to convince us, that between copper and cholera there exists any such antagonism as he claims to have discovered.

GEORGE JOHNSON, M.D.

Egypt as a Health Resort, with Medical and other Hints for Travellers in Syria. By A. DUNBAR WALKER, M.D. 12mo, pp. 139. London: J. & A. Churchill, 1873.

The Climate of Egypt and Nubia, with Medical Hints to Invalids, &c. By JAMES STIRTON, M.D. 12mo, pp. 46. Glasgow: D. Robertson, 1872.

The Romans sent cases of phthisis and of hæmoptysis to Egypt; and Pliny the Elder was uncertain whether the benefit which they derived was got from the climate of Egypt or from the sea-voyage, which was a famous remedy for such complaints in those days. If they did not proceed further than Alexandria and its doubtful climate, as would seem from Celsus often to have been the case, doubtless it was the voyage that did the most good.

Of late years, we moderns have begun to send the same class of patients to Egypt; and undoubtedly there are few better winter resorts for those who require a dry and warm climate, than Cairo and the Upper Nile, the latter of which can now be reached more conveniently in the Khedive's steamers, than by the old process of ascending the river in Nile boats. But, as Pliny mentions a consul having gone for hæmoptysis, and as his nephew sent a favourite freedman, so in our day it is only the comparatively wealthy that can undertake so expensive a journey. A residence even in Cairo is more costly than in the towns of the Riviera.

Dr. Walker has compiled his little book to assist invalids who visit Egypt, or who venture on what he justly describes as the less advisable journey for such as are delicate, a visit to the Holy Land and Syria.

The advice he gives is on the whole judicious, but consists very much of commonplaces about matters, with which travellers are now-a-days very generally familiar; and we should scarcely have expected them from one like the author, who tells us that he has visited most health-resorts in Europe, and in parts of Asia and Africa.

Dr. Walker's English is throughout slipshod, as when he spies out in Alexandria 'ladies possessed with classic features,' or, as when he tells us in his preface, that his book 'is an exposition of the diseases met with, giving precautions how they may be avoided, and those that are benefited by a residence in the country;' nor are his powers of generalisation very profound, when he observes, that 'the light-heartedness and flippancy of the French, Italians, and Arabs, is generated by the sunshine and the eternal blue acting on their character.'

The medical information is not very definite. The climate of Egypt is declared to be useful in every stage of phthisis. Plague, he tells us, is the curse of Egypt, but happily only makes its appearance at certain periods. We presume that he has seen no case of it.

We should have been glad to get some detailed account of the accommodation afforded by the villages of the Lebanon, and of the expense of a residence in them. But on this, and on their climates, almost the only subject on which he might have given some novel information, Dr. Walker is all but silent. Notwithstanding its many shortcomings, his book is not without a sort of use.

Although Dr. Stirton appears to have paid only one visit to Egypt, and that as long ago as the year 1859, still his little work contains a good deal of useful practical advice for travellers.

These works do not profess to give a full account of the climates, which they recommend.

J. MACPHERSON, M.D.

MISCELLANY.

THE EVIDENCE IN THE WEST HADDON CASE.—No little surprise is expressed by scientific medical men at the evidence of the expert at the disastrous inquest on Mrs. Gulliver, that the alleged heat of a body after death warranted the conclusion that 'a noxious volatile substance had been administered, and had caused death, of which, however, he found no traces.' The result of this statement, made to a village jury whose minds were impressed by the local gossip which had led to exhumation, was a verdict of 'death by poison.' Mrs. Waters, the victim of this verdict, courted death rather than face the fearful ordeal before her. Mr. Rodgers is, we think, bound to state on what grounds he made the reckless assertion which led to such fearful consequences. The substitution of a wild hypothesis for a state of doubt is certainly not in the province of a chemical expert on oath, in a case involving capital charges. The matter cannot, in the public interest, be allowed to rest in its present position of doubt. The sole test of temperature appears in this case to have been the recollection of an impression conveyed to the hand; and on this subject Dr. A. S. Taylor and Dr. Wilks remark truly: 'The condition of the hand itself may lead to an erroneous impression. If the two hands are of different temperatures, a recently dead body may appear cold to one, and warm to the other.'

THE SANITARIUM OF THE ASHANTEE EXPEDITION.—A correspondent in St. Vincent writes to us.—'I saw Surgeon-Major Mackinnon at Madeira, and he told me

that he was no further forward with the Sanitarium for the Ashantee expedition than when he landed, as the authorities at Madeira are so afraid of disease being imported into the island that they throw every obstacle in his way, and so far have completely prevented him from even making a commencement. From an English resident I heard that the governor and health officer, and all the inhabitants, were very strongly opposed to their island being put to such a use, and that it is certain that any vessel arriving from the coast with wounded, and having a single case of fever on board, would be put in quarantine, and not a single person would be allowed to land. So St. Helena must be the place after all. I see by Wyld's map it is only 1,275 miles from Cape Coast, and could be done in six days; besides, the run would be directly away from the coast instead of along it, as the run to Madeira is. This place, St. Vincent, is hot and barren, but has a splendid natural harbour.'

PEPSIN IN OYSTERS.—It appears, from some experiments made by Mr. E. H. Haskins (*Boston Medical and Surgical Journal*), that raw oysters contain pepsin enough to digest themselves. No wonder oysters agree with most dyspeptics.

POISONING AT MASS.—The *Indipendente* of January 5 quotes from the *Gazzetta di Bergamo* a statement that four priests and two friars were simultaneously attacked with abdominal pains and vomiting soon after celebrating mass on December 22. The vessel from which the wine used in the mass had been taken was found to contain a white sediment—apparently tartar emetic. A priest has since then been taken into custody on suspicion of attempting to poison his brethren.

ACCORDING to a French journal, horses and other animals may be protected from the persecutions of flies by painting with a pencil the insides of the ears, or other parts liable to be bitten, with a few drops of empyreumatic juniper oil (*huile de cade*).

PROFESSOR NAMIAS, of Venice, has recently died after a short illness.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, JANUARY 28, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

DUPUY ON FERRIER'S EXPERIMENTS ON THE BRAIN.*

Dr. Ferrier's experimental inquiry into the motor functions of the cerebral convolutions in mammalia has attracted so much attention, and awakened so keen an interest among physiological students, that, while awaiting the further prosecution of his researches, it cannot but be interesting to them to learn that a similar series of experiments have been recently undertaken in France by Dr. Eugène Dupuy, a former pupil of Dr. Brown-Séquard.

It will be remembered that the experiments of Dr. Ferrier, besides demonstrating that, under certain conditions, electrical stimulation of the convolutions may determine epileptiform and choreic convulsions, tended more particularly to establish the centralisation of certain groups of adaptive movements in particular localities. Stated broadly, the motor endowments of the paws, legs, and tail in dogs and cats were found to be centralised in the 'superior external convolution,' immediately before and behind the crucial sulcus; while the fore part of the 'middle external convolution' appeared to govern the movements of the eyelids, eyes, and parts of the face; and, lastly, the 'inferior external' and 'Sylvian convolutions' those of the mouth, tongue and jaws. As regards the posterior parts of these convolutions, the movements obtained were few and less determinate, chiefly of the ears and head; while in his later experiments Dr. Ferrier is reported to have obtained indications of centres of special sense—sight, hearing, smell—in that situation.

We translate so much of Dr. Dupuy's paper as describes his own experiments, undertaken with a view to the verification of the results obtained by Dr. Ferrier, and the general inferences which he draws from them. It will seem that they differ in some important respects from those of Dr. Ferrier, and principally in yielding much less determinate phenomena, while they also suggest that the movements obtained by Dr. Ferrier are referrible not so much to the convolutions themselves to which the electrodes are applied, as to the propagation of the electric currents to the nerves or ganglia at the base of the brain.

Without venturing to express an opinion as to how far the differences in the results obtained may be due to differences in the method of experimentation—the mode of applying the electrodes and the strength of the current,—or how far Dr. Dupuy's interpretation of them may be accepted, we think the facts presented

are such as to call for some elucidation from the experimenters.

'We have repeated,' writes Dr. Dupuy, p. 21, 'the experiments of Ferrier, as well as those of Fritsch and Hitzig, but in this instance with some variations.'

'1. In a dog, incompletely anæsthesiated, in which the brain had been exposed without subsequent hæmorrhage (by the aid of a galvano-cautery), I succeeded very well, by electrising with an induction current after the manner of Ferrier, in producing contraction of all the muscles of the shoulder and paw of the side opposite to that to which the electrodes were applied (the convolutions immediately above and in front of the fissure of Sylvius).

'2. In applying the electrodes to point 19,* I again produced movements in the whole of the anterior and opposite part of the body.

'We have never succeeded in obtaining the results indicated by Dr. Ferrier, as far as regards the projection of the tongue and the movements of the eyelids, &c.

'We ought to observe that we have always made use of ether, and that the dogs submitted to experiment have been *incompletely* anæsthesiated. On several occasions, when the animals had recovered a little, we have observed shocks of the muscular masses, but shocks "*en bloc*" which Ferrier calls choreic movements. In guinea-pigs, by applying the electrodes on two symmetrical points in the middle region of the hemispheres, we have produced a genuine attack of opisthotonos, but never an epileptic paroxysm; yet it is well known that guinea-pigs have very smart attacks of epilepsy as a consequence of different nervous lesions. Similarly, we know that dogs become sometimes choreic; yet we have never succeeded in producing, as Ferrier has described, phenomena resembling chorea in dogs. But if Ferrier now quickened, now slackened, the interruptions of his apparatus, he would have seen the muscular shocks keep pace with the interruptions even to tetanisation; it is this which he has taken for chorea and "*fits*."

'3. In a second series of experiments, we injected some atropine into a dog of strong build and not etherised; on applying the electrodes to point 15,† we produced contractions identical with those which we had previously observed, and always crossed; that is to say, contraction of the whole fore-paw of the opposite side, together with a contraction of the muscles inserted into the occipital and parietal bones, which had been previously cut at their cranial insertions and turned back.

'4. To another strongly built and vigorous dog, we administered a strong dose of haschisch without etherisation; on applying the electrodes to points 14 and 18,‡ we produced excessively strong contractions through the whole frame of the animal, which struggled furiously and barked like a watchdog.

* The numbers throughout refer to Dr. Ferrier's diagrams in his paper in the *West Riding Lunatic Asylum Reports*, vol. iii. 1873. No. 19 in the dog is situated in the inferior external convolution anterior to the Sylvian fissure, and the excitation of that point by Dr. Ferrier occasioned a drawing up of the opposite side of the face and closure of the jaws.

† No. 15 is at the frontal extremity of the superior external convolution, and is included by Ferrier among the centres of motion for the eyelids and eyes.

‡ Nos. 14 and 18 are in the anterior part of the inferior external convolution, and included by Ferrier among the mouth-centres.

* *Examen de quelques Points de la Physiologie du Cerveau.* Par le Dr. EUGÈNE DUPUY. Paris: Ad. Delahaye. 1873.

'We etherised the animal, and then observed that electrification of the same parts still gave very closely analogous results, but very feeble; no crying.

'5. In another strongly built and very healthy dog we applied the electrodes on point 24* after complete etherisation, and we then obtained no muscular contractions.

'6. In the same dog, after being allowed to recover, we injected three decigrammes of strychnine (*sic*), and then, by exciting points 23 and 25,† we produced veritable convulsions no longer limited to a single half of the body.

'7. In another dog, after incomplete etherisation, we applied the electrodes successively on points 1, 6, 5,‡ and we observed movements always crossed and limited to the fore-limb, but extending to the whole side of the body when the current was strong.

'8. We completely anaesthetised this dog, and applied to point 17§, and to the points marked by crosses,|| the nerve of a galvanoscopic frog insulated on a plate of glass; every time that the points 23, 25, 24, &c., in the anterior part of the hemispheres were touched with the electrodes, the foot of the frog underwent violent contractions, and we observed some movements in the anterior and opposite limb.

'9. In a very strong dog we removed by aid of a fine curved scalpel the opto-striated bodies of one side, penetrating by the great cerebral fissure, the corpus callosum being divided. The animal being feebly anaesthetised, we applied the electrodes to points 4, 18, 6, &c., and produced, when the current was strong, not only contractions in the anterior and opposite limb but also in the posterior limb.

'10. In a healthy dog which had served for one of the previous experiments and fairly recovered, after complete etherisation, we exposed the sciatic nerve of one side, and one of the gastrocnemii muscles, on glass plates, leaving the latter in connection with the rest of the animal by a nervous band. Each time that the electrodes (strong current) were applied to points 24, 23, 1, &c., on the hemisphere of the opposite side to that of the exposed muscle, no contraction occurred in it, but the direct excitation of the sciatic nerve made the muscle contract.

'11. In a dog which had already served for one experiment, we removed the cerebral masses as far as the level of the pons Varolii, and we applied the electrodes to the surface of the section; we then obtained contractions always of a limited kind, and in the right or the left fore limb; it was not possible to tell if the effect was crossed, because of the removal of the hemispheres.

'12. In one of the animals submitted to experiment, on electrifying the dura mater at the level of the wound, we observed the anterior, and sometimes opposite, paw contract.

'We made use in all the experiments of the electric apparatus of Du Bois-Reymond, and we have repeated them a great many times.

'We could have wished to trace the alterations of

sensibility following localised electrification, but it has not appeared to us to be practicable; we have merely ascertained that, in the greater number of the dogs experimented on, the electrification of points situated approximately at the posterior part of the cerebral hemispheres gives rise to very evident muscular contractions, and we have frequently provoked cries from the animals when they have been feebly anaesthetised. It is worth noting here that, in one of the animals, we removed the whole of the upper surface of one cerebral hemisphere; the animal lived four days, after which period it was killed. It had no appreciable paralysis, it did not drag the limb, and on the first day, when it had completely recovered of the anaesthesia, it started off walking in the courtyard of the laboratory, it ate, and barked when irritated; the day following the operation it remained always in a crouching attitude, and did not walk about unless we excited it. Traumatic fever had set in.

'Ferrier, as we have said above, is led by his experiments to adopt the doctrine that each group of cerebral convolutions is a centre of innervation for the motor or sensitive nerves of a certain territory; he is so far in perfect accord with Meynert, when the latter considers the cortical layer as a 'Plane of Geometrical projection,'* but he parts company with him when Meynert maintains that this cortical layer has not the faculty of originating sensations, nor of spontaneously transmitting the orders of the will to the muscles. Ferrier furthermore states in his conclusions that his experiments confirm in all points the hypothesis of Dr. Hughlings Jackson, who believes that the muscular spasms or paralytic symptoms which are observed in epileptic and paralysed persons may be referred to lesions of some part of the surface of the brain. We could cite here a number of most important necropsies of epileptics, where lesions have been found everywhere except in the cortical layer; so also of the cornu Ammonis, where Meynert places the seat of epilepsy; but experiment again serves to destroy this hypothesis, for it is well known that our distinguished master, Brown-Séquard, has shown that attacks of epilepsy may be produced in guinea-pigs after the whole of the encephalic mass has been removed. These experiments being very familiar, and repeated a great many times by ourselves, it seems useless to recapitulate them here.

'We shall not analyse the experiments of Ferrier, because we have already given them entire in an earlier part of this paper. By comparing them, we shall see that very often he has obtained very nearly the same results on irritating different parts of the cortical layer.

'It seems to us, however, exorbitant to deduce from his experiments the conclusions which we have transcribed from his paper, for our experiments have

* 'Since, now, this organisation effects the contact of the sensory shell of the cortex of the cerebrum with the various forms of sensory impressions derived from the external world, the image of which is coincidentally projected upon the cortex, the name of *projection system* is very appropriate to this great segment of the nervous system, and in this comparison the cortex of the cerebrum is to be regarded as the surface on which the projection is received, while the external world stands for the projected object.

'As the movements of the body constitute the source of certain kinds of sensation (muscular sensations), so do they also form a part of the external world projected upon the brain.'—Th. Meynert's *Survey of the Brain*, translated by H. Power.

* A point on the suprasylvian gyrus just anterior to the fissure of Sylvius.

been made under the conviction that we should obtain the same results as he did, whereas we believe we are only authorised to arrive at the following conclusions.

'I. It is possible, by irritating certain limited points of the cortical layer of the brain, to produce contractions sometimes of an entire limb.

'II. Generally it is the fore limb, and of the opposite side to that of the point of irritation, which is the seat of contraction.

'III. The electrical current must be propagated to the base of the brain in order to excite it; either to the nerves which arose there, or the base itself or bulb.

'IV. If the dura mater be excited by electricity, we also obtain contractions in one of the fore limbs, generally in a crossed manner.

'V. The fact that a galvanoscopic frog has been thrown into a state of contraction when its nerve touched a part of the cerebral mass far from the point of excitation, confirms the idea that the electric current is propagated.

'VI. Contrary to the results obtained by Ferrier, we have never succeeded in obtaining the effects upon the tongue, whether of projection or of retraction.

'VII. The whole of the cortical layer of the brain is probably a centre of reflexion of a certain kind of sensibility, capable of acting in a reflex manner on motor or sensitive centres, but its integrity is not indispensable to the manifestation of voluntary and even intelligent actions.

'VIII. In the case of the animals on which I experimented, it was possible to excite contractions of the muscles of an entire limb on the opposite side of the body, even after the removal of the opto-striated bodies of the opposite side.'

EDWARD LIVEING, M.D.

LUSSANA AND OTHERS ON THE PORTAL CIRCULATION AND THE BILIARY SECRETION.

F. Lussana* quotes several experiments of Schiff's, which show that part of the bile which is poured into the intestine is again absorbed from it, and is carried by the portal vein to the liver, whence it is again excreted into the intestine. When ox-bile is injected into the duodenum of a dog with a biliary fistula, the quantity of bile secreted by the liver is increased. The increased secretion is not due to the bile which was injected into the intestine stimulating the liver to form more bile, but simply to the injected bile being excreted by the liver. This is shown by injecting ox-bile into the duodenum of a guinea-pig. The guinea-pig's bile does not usually give Pettenkofer's reaction, but it does so after the ox-bile has been introduced into the duodenum. Part of the bile is expelled with the fæces, after being reduced to its solid constituents, glycin, taurin, and dyslysin. Another part remaining unchanged in the liquid condition is absorbed. There is thus a constant circulation of bile going on between the intestine and the liver without any of it passing into the general circulation, or, in other words, without the animal becoming jaundiced. The whole of the principles contained in the bile secreted in any given

time are ultimately to be found in the excrements; but the quantity of biliary constituents contained in the fæces voided in any fraction of that time may not correspond in the least to the quantity of bile secreted during that fraction.

The author next shows that iron and mineral poisons may circulate in the portal system in the same way as bile, without entering the general circulation. According to Quevenne, the liver is the organ by which iron is principally excreted; and Bouchardat found iron constantly in the bile of animals to which iron had been given. Bouchardat, Quevenne, and Gelis have also observed that no iron appears in the urine, even after prolonged administration; but several experiments which were made in Lussana's laboratory by Paganuzzi have shown that citrate of iron appears in the urine when it is injected directly into the blood.

Lussana therefore concludes that, when iron passes through the kidneys before it passes through the liver (as after injection into the veins) it is eliminated in the urine as well as in the bile. When it passes through the liver before it reaches the kidneys (as it does when swallowed) it is eliminated entirely by the bile. The fact that it is absent from the urine, or only appears in it exceptionally and in the minutest traces, even after its prolonged administration, is no proof that iron has not been absorbed or is present in the portal circulation; it only shows that it has not passed through the liver and reached the general circulation. However, when iron is present in the blood in a notable quantity, it can be, and is, eliminated by the urine. When small doses of iron are taken they are completely absorbed, and passing with the portal blood to the liver are excreted in the bile.

Ignorance of this entero-hepatic circulation of iron is the cause of the difference of opinion regarding the best mode of using this remedy between experimentalists and clinical observers. The former, having noticed that nearly all the iron swallowed appeared in the fæces, even when only one small dose was taken, naturally concluded that it was not absorbed, and advised its administration only in homœopathic doses, considering larger ones to be useless and irritating. The latter, on the contrary, have obtained the best results from the use of large doses, especially in diseases of the abdominal organs. This is due to the action of iron upon the hæmatinic functions of the liver. Iron taken in large doses by the mouth is absorbed by the veins of the gastrointestinal canal, is carried to the liver by the portal vein, passes through the capillaries of the liver, is eliminated in the bile, passes again by the biliary duct into the intestine, and is expelled along with the fæces by the anus. The whole, or nearly the whole, of the iron taken by the mouth will thus appear in the fæces in the same way as if it had passed directly down the intestinal tube without being absorbed at all; but the large quantity of iron which is found in the bile after the administration of the medicine, suffices to show that a large quantity is really absorbed and circulates in the manner indicated.

Iron is not the only substance which circulates between the intestines and liver without entering the general circulation. Manganese, copper, iodide of potassium, lead, bismuth, tin, silver, gold, zinc, mercury and antimony seem to do the same; and they may thus remain in the body for a long time without being eliminated by the urine.

Curare, also, when taken by the mouth, may remain in the entero-hepatic without reaching the systemic

* 'On a Lesser Circulation between the Liver and Intestine (Entero-hepatic Circulation), and on the Reflux Hepato-renal Circulation.'—*Lo Sperimentale*, Oct. 1872.

circulation; and this is one of the reasons why it is not poisonous except when taken in considerable doses by the mouth, while a small quantity proves fatal when it is introduced directly into the veins. [It should not be forgotten that another reason is, that curare is only slowly absorbed from the intestinal canal, and is eliminated by the kidneys while absorption goes on. When the kidneys are extirpated or the renal vessels tied, the animal is poisoned, as Bernard and Hermann have shown. This fact also indicates that the curare passes into the general circulation and is not limited merely to the entero-hepatic one. The same is probably the case with other substances, and Schiff considers it to be so with bile.—*Rep.*] Lussana gives several experiments which prove that the lethal properties of curare are not lessened by the saliva, gastric juice, bile, or pancreatic juice. Saliva and pancreatic juice sometimes appear to do so, but this is merely due to the viscosity of the mixture impeding absorption. Curare can be detected in the bile after it has been given by the mouth. A dose which proves fatal when injected into the systemic veins produces no bad effects when injected into the mesenteric veins, as in the latter case it remains in the entero-hepatic circulation without reaching the systemic one.

If the dose be too large, it will not all be eliminated from the portal blood by the liver, but will enter the systemic circulation and produce symptoms of poisoning. The quantity which the liver of a medium-sized dog excretes each time that the blood it contains is changed, is not less than half a centigramme, and not more than a centigramme.

Lussana believes that the impunity with which the poison of the viper can be swallowed is due to its being retained in the entero-hepatic circulation. [As iron is eliminated by the liver even when it has been injected into the systemic circulation, it seems probable that other substances are so also; and if this be the case with the poison of the viper or cobra, emetics and purgatives may prove useful adjuncts to other treatment.—*Rep.*] Fontana found that curare administered internally in large doses killed rabbits and guinea-pigs, and Moroni and Dell'Acqua have shown that it is those animals which have an imperfect entero-hepatic circulation, i.e., in which the blood can pass collaterally from the mesenteric veins to the vena cava without passing through the liver (reptiles, birds, rabbits, guinea-pigs and cats) which are least able to resist the action of curare administered by the mouth.

They have laid down the rule, that the susceptibility of animals to the toxic effects of curare introduced into the alimentary canal is in proportion to the development of the collateral circulation of the liver; the larger and more numerous the veins which establish a direct communication between the portal vein and the vena cava, the more easily does poisoning occur, and *vice versa*. In fishes, reptiles, and birds this communication is effected by the venous system of Jacobson, and in mammals by means of anastomoses between branches of the portal vein and the vena cava and azygos vein. [In man there are also anastomoses between the mesenteric veins and those of the abdominal walls, which become greatly enlarged when the circulation through the liver is obstructed, as in cirrhosis (*Henle's Handbuch der Anatomie*, vol. iii. p. 373). If we assume this rule to hold good for metallic substances as well as curare, it will greatly assist us in understanding the susceptibility of some individuals to

mercury, etc., and the effect of diseases of the liver upon the action of medicines.—*Rep.*]

Bernard was led to believe that there was a reflux hepato-renal circulation, and that the blood of the hepatic vein passed down the vena cava and into the renal veins, from the rapidity with which substances appeared in the urine after their introduction into the intestinal canal, and still more from the fact that, when a considerable dose of atropia is given to a rabbit, it will not be poisoned, though the atropia appears in the urine in such quantities that a few drops of it put into the eye of another rabbit will cause dilatation of the pupil. He concluded that the poison had passed directly from the portal vein to the kidneys without entering the general circulation. Although his facts were right, Lussana thinks his conclusion was wrong, and that the poison did enter the general circulation, its apparent non-effect being simply due to the great power which rabbits possess of resisting the action of the poison.

Shaw has found that, when quinine is administered internally, only a small fraction of it is excreted by the urine, the remainder appearing in the faeces. Notwithstanding this, it is found that large doses are required in the treatment of intermittent fevers. If we suppose that as the gravest lesions the miasmatic poison occasions are in the liver and spleen it exerts its action chiefly on the portal system, we can readily comprehend how this powerful antiperiodic may exert its influence chiefly while in the entero-hepatic circulation without much of it entering the systemic vessels. [If we assume that fever-poisons circulate in the same way, we can at once understand that the old treatment of emetics and purgatives administered at the onset of the disease may have a beneficial effect.—*Rep.*]

Heidenhain and Laffter* have repeated Schiff's experiments on the absorption of bile from the intestine and its re-excretion by the liver, but have employed guinea-pigs instead of dogs. Instead of the secretion of bile being much increased after the injection of bile into the intestine, it became rather less than before. They attribute this, however, only to the disproportion between the size of the animal and its enormous secretion of bile. A very considerable proportion of the water in the organism is lost in the bile, and the water from the bile injected into the intestine is not absorbed with sufficient rapidity to compensate for it. In dogs or large animals, the loss of water is much less as the bile is more slowly excreted, and bears a very much smaller proportion to the size of the animal. They found, however, in confirmation of Schiff's results, that the percentage of solids in the bile excreted is increased after the injection. They consider that this increase is due to the bile injected into the intestine passing directly through the liver, and not to its indirect action causing increased formation of bile in the liver. The proof which Schiff gives of this, viz., that the guinea-pig's bile gives Pettenkofer's reaction after the injection and not before, is not altogether to be relied upon; for, when the test is applied to the normal bile of the animal with Neukomm's modification, it succeeds perfectly. They found, like Schiff, that the colour of the bile secreted becomes darker after the injection; but this occurs so quickly that it seems hardly possible that it could be due to the colouring matter of the bile absorbed from the intestine. On repeat-

* Laffter, *Experiments on the Physiology of the Biliary Secretions*. Inaugural Dissertation. Breslau, 1873.

ing the experiment, however, with tincture of rhubarb and sulphindigotate of soda instead of bile, they were able on several occasions to detect the colouring matter of the rhubarb or the indigo in the bile secreted, within one minute after these substances had been injected into the intestines. The indigo appeared in the urine in one case seven, and in another nine minutes, after its appearance in the bile.

With a view to determine whether the composition of the bile is altered when an obstruction is presented to its exit and biliary congestion takes place, a series of experiments was instituted. These were performed by tying the bile-duct, and analyzing the bile before and afterwards. They gave the following results.

1. The rapidity of the secretion of bile was found to be diminished. The experiments having been made upon guinea-pigs, this diminution is not to be ascribed entirely to obstruction of the flow of bile.
2. The percentage of solid constituents does not undergo any constant or important change. This shows that in biliary congestion the water is not removed while the solids are left, but that all the constituents of the bile are absorbed equally. Heidenhain has found that atropia paralyses the secreting nerves of the salivary glands (vide *London Medical Record*, vol. i. p. 18), but neither it nor physostigma seem to have any influence upon the secretion of bile. Nicotia causes a slight acceleration of the flow of bile at first. This is not caused by increased secretion, but is due simply to the contraction of the muscular fibres of the gall-ducts occasioned by the nicotia. Rhubarb is generally considered to be a cholagogue, but it does not increase the secretion of bile, although it passes through the liver and can be detected in the bile. Sulphindigotate of soda likewise does not increase the secretion.

T. LAUDER BRUNTON, M.D.

ABSTRACT OF A CLINICAL LECTURE ON
METEORISM. BY THE LATE PROFESSOR
OPPOLZER, OF VIENNA.*

(Continued from page 35.)

If we now proceed to make a closer examination of the condition which gives rise to meteorism, and which has been generally connected with the presence of intestinal catarrh, we find, as daily experience abundantly teaches, that on the one hand there are a not insignificant number of cases, in which intestinal catarrh is present, and in which, nevertheless, the intestine is not only not distended beyond the normal degree, but does not even exhibit the normal amount of distention, being, on the contrary, remarkably contracted; while, on the other hand, cases may be observed, especially in exanthematic typhus, in which there is no infiltration of the intestinal glands and no excessive intestinal secretions, and in which nevertheless meteorism is present in a very high degree.

Since, then, on the one hand, meteorism may not only be absent, but the intestines may be contracted, in cases of intestinal catarrh, and, on the other hand, meteorism may be developed and reach a high degree in circumstances apparently unfavourable to its production, it is plain enough that the affection of the intestines cannot be regarded as the cause of meteorism, and consequently cannot in any way be considered as connected with the

existence of this troublesome accessory of so many diseases.

With regard to the other prevalent views and hypotheses on the subject under consideration, we will here refer only to those which assume that meteorism must either be developed from the remains of the food present in the intestines, that is, from the contents of the intestinal canal, or must be ascribed to the changes undergone by the faecal masses accumulated in the bowels. But that such views must also be regarded as quite incorrect, we shall again see from a brief examination of the conditions which lie at the foundation.

It is impossible to deny the existence of a rather large number of cases, and no observer of experience can dispute their existence, in which—as one may readily be convinced when there is an opportunity of making a *post mortem* examination—although very considerable meteorism has been present during the course of the disease, yet no contents can be found in the intestinal canal, or at least only a very small quantity of mucus is to be seen, which cannot for a moment be regarded as the causal and essential condition of the meteorism. The reason why no contents are to be found in the intestines is simply this, that in consequence of the diarrhoea which has occurred some time previously, and before the meteorism has been developed and has become evident, the faecal masses accumulated in the intestine have been evacuated, so that in making the necropsy nothing more of them is to be found. But if the whole of the faeces in the intestinal canal have been discharged some time before the appearance of meteorism, and if, in spite of this, meteorism is subsequently developed, it is incontestably correct to draw the conclusion that the contents of the intestinal canal or the changes which they may undergo in the bowels can have nothing to do with the meteorism.

From these considerations it becomes self-evident that all the explanations which have hitherto been given of the cause of meteorism, and to which it has been believed necessary to have recourse in the absence of any other more probable explanation, throw no light on the true causes of the development of meteorism; and that hitherto it has only been possible to frame altogether vague hypotheses as to the condition to be regarded as the primary cause of meteorism, because it has been thought erroneously that the causes were to be sought for in the very place where they are not to be found, and especially as their existence ought to be sought in another place on which too little attention has been bestowed.

The views regarding meteorism, here alluded to and refuted, are still constantly paraded forth in the newest works of the most eminent medical authors. And meteorism itself is passed by with a scarcely credible laconic brevity and with astonishing indifference, only a few words, reaching back into the grey antiquity of theories, being dedicated to it *en passant*.

Oppolzer was led by the abundant and excellently applied opportunities which he possessed, to adopt the view that the spinal cord has an influence in the development of meteorism which has hitherto been neglected, and that the cause of meteorism is to be specially sought in the nervous system. It is an observation established by experience at the bedside that, the weaker an individual is, the more intensely is meteorism developed. For this reason, Oppolzer

* *Allgemeine Wiener Medizin. Zeitung*, Jan. 20, 1874.

was of opinion that meteorism is dependent on a paralysis of the nervous system, and that its occurrence must be regarded as an ominous symptom, inasmuch as it denotes that the sympathetic system is involved in the disorder.

(To be continued.)

LABADIE LAGRAVE ON CARDIAC COMPLICATIONS IN CROUP AND DIPHTHERIA.

IN a thesis lately published by M. Labadie Lagrave, the author clears up some obscure points in the history of diphtheria. He says that the majority of modern writers agree in vaguely referring the fatal result which frequently terminates this affection to a sort of general blood-poisoning; to a primary diphtheritic infection in some persons, to a secondary in others; but to which the imperfect state of modern hæmatology does not allow the true character to be assigned. Would it not, however, be possible to assign a more precise cause and starting-point for these mortal accidents? The author has partially replied to this question by describing a collection of lesions resulting directly from the injection of the blood in diphtheria, obtained from the analysis of a hundred cases, nearly all observed by himself.

Though M. Labadie Lagrave has specially given his attention to the cardiac complications of this disease, he has set forth the various anatomical lesions of the body with which he has met in the different organs. In regard to these, he has arrived at the following results. Vegetating acute endocarditis with fibrinous deposits, which are frequently the cause of embolism, are present in the heart in twenty-one out of forty instances. The lungs frequently contain nodules of pulmonary apoplexy or sanguineous infarctus, probably due to arterial or capillary embolism. These organs also show small venous thromboses between their lobules. Sanguineous infarctus sometimes occur beneath the pericardium, between the impaired fibres of the heart, and occasionally in the subcutaneous cellular tissue. Venous thromboses exist in the pia mater, in the brain, in the sinuses of the dura mater, in the liver, and in other parts of the body. In cases of malignant diphtheria, the muscular fibre of the heart is often degenerated (myocarditis); sometimes also the internal wall of the smaller arteries is itself inflamed (proliferating endarteritis); the kidney-substance has also degenerated (parenchymatous nephritis); and leucocytosis and albuminuria are frequently met with in connection with these lesions.

Endocarditis is the most common of all these lesions, and M. Labadie Lagrave has specially applied himself to its study. Passing to the clinical part of the work, we perceive the importance which the diagnosis of this complication may have; the diagnosis being often rendered very difficult by the latent and insidious progress of the disorder, as is likewise observed in most cases of secondary endocarditis. The danger thus run by the patients is easily seen. The endocarditis in its first stage not only impedes and complicates the course of the primary disorder, but it may in its subsequent course produce sudden or speedy death by favouring the formation of intra-cardiac clots, or may finally carry off the patients by the gravity or the extent of the cardiac accidents. These accidents may assume various forms. Sometimes the cardiac thrombosis brings on the death of

the patient in a few hours, after a more or less prolonged period of true asphyxia; sometimes death does not ensue until two or three days after the symptoms have appeared. M. Labadie Lagrave cites a more uncommon complication, which occurred in a child on whom tracheotomy had been performed. The little patient was seized with hemiplegia, and died with softening of the brain produced by arterial hæmorrhage. Endocarditis, however, is not always fatal, the book recording two well-authenticated cases of cure. The most important points to be gathered from the clinical teaching of M. Labadie Lagrave's interesting work are, that cardiac complication frequently exists in diphtheria, bringing on, when it is in relation with croup, symptoms which may simulate attacks of dyspnoea produced by obstruction of the trachea, with which it is important not to confound them. This diagnosis is equally useful both for prognosis and for treatment.

MEDICINE.

BULL ON PERITYPHLITIS.—This is an inaugural thesis, to which the New York Faculty of the College of Physicians and Surgeons awarded the first prize, and is reprinted from the *New York Medical Journal*, September, 1873. It contains, in a condensed form, a summary of almost all that is known of this disease, as regards etiology, anatomy, symptoms, and prognosis. But the best part of the treatise is the remarks on treatment, which appear to be not only judicious but worthy of quotation, at least in part. After enjoining absolute rest, and the avoidance of purgatives, as in typhlitis, together with a well-regulated diet, the use of opiates, ice, and carbonic acid in solution to check vomiting, Dr. Bull proceeds: [his remarks are here somewhat abridged].

‘When suppuration occurs, it must be hastened by warm applications, poultices, &c., to the tumour; and opium and the same general measures should be continued as before. Formerly this plan of treatment was pursued until the abscess pointed externally, when it was opened, or burst in some other direction.

‘Within a few years, however, the practice of opening these abscesses at once, without waiting for the appearance of fluctuation, has been adopted by Professor Willard Parker, of this city, and employed with success by himself and others. The propriety of the early opening of these abscesses was discussed by the earliest writers on this subject. Dupuytren was averse to the operation, because of the frequent occurrence of opening into the cæcum, and its happy results. Grisolle favoured it, as he observed that two out of ten cases in which opening into the cæcum occurred ended fatally, and that evacuation of the pus by the natural passages was often followed by external opening and death. Velpeau advised early evacuation of these abscesses; and Battersby, in his complete review of the subject of iliac abscesses, recommended it. Dr. Martin, of Lyons, in 1835 advised the application of caustic potash. Bourienne relates a case, in which a surgeon cut down to evacuate the pus, found none, was much laughed at, but the next day a free discharge took place through the wound, and the patient recovered. Mr. Hancock (*Lancet*, Sept. 30, 1848), opened such an abscess, and recommended a similar proceeding in all such cases. Dr. Willard

Parker again called attention to it, and successfully treated a case in this way. Further study of the disease gives us additional and even stronger reasons for the adoption of this plan of treatment. When the abscess opens externally, we find the danger to life from exhaustion to be extreme. Even when the pus has been discharged into the cæcum, suppuration has been prolonged till death ensued, and subsequent opening, either externally or into other organs, has occurred with fatal results in one half the cases. Pyæmia is seen to be a not unfrequent complication, doubtless induced by the thrombosis of large veins encroached upon by the growing abscess. Empyæma, fatal hæmorrhage from the erosion of large blood-vessels, perforation of almost every hollow abdominal and pelvic viscus, are all complications which arise from allowing these abscesses to run their course unmolested; all may be avoided by giving vent to the pus before it accumulates in sufficient quantity to render liable the occurrence of any of them. Dr. Stiegle (*Württemberg Correspondenz-Blatt*, vol. xi.), reports two cases, and Dr. Weber one. Of the six cases thus collected, in which, on the evidence of the symptoms, and the presence of the tumour, and without perceptible fluctuation, the abscess has been opened, five have been followed by recovery. In the one fatal, the patient was exhausted before the operation was resorted to. The knife is undoubtedly the best instrument for evacuating these abscesses.* Dr. Bull discusses the objections to the use of Vienna paste and puncture with a trocar; but inclines to the use of the aspirator, or even to a second or third trial of this instrument. A table of the six cases referred to, two by Dr. Parker, one by Dr. Weber (*New York Medical Journal*, August, 1871), one by Dr. Stiegle, and one by Dr. Kottmann, is appended; the pamphlet contains also almost a page of bibliography.

WILBRAND ON A SIMPLE METHOD OF FORCIBLY INJECTING LARGE QUANTITIES OF FLUID INTO THE INTESTINAL CANAL.—The *Berliner Klinische Wochenschrift*, Dec. 8, 1873, contains a paper by Dr. L. Wilbrand, which was written before the publication of Dr. Mosler's article, of which we lately gave a summary,* in which he recommends the use of an irrigator, such as is now commonly met with in our hospital wards for washing out wounds (i.e., a cylindrical vessel to hold the fluid, with a long flexible tube, and a nozzle or stop-cock), for injecting fluids into the bowels. He narrates an interesting case of obstruction, apparently in the small intestine, occurring in a female patient, aged twenty-two, after ovariotomy. Whilst in hospital, the obstinate constipation from which she suffered was overcome by 'electric' apparatus (probably faradisation). He had not a battery at hand, nor a long (O'Beirne's) tube; and an ordinary clyster-apparatus produced no effect. Meanwhile, the patient's condition grew worse. She was much prostrated, her extremities were cold, her pulse scarcely distinguishable, and respiration was greatly embarrassed. Under these circumstances, he bethought him of the irrigator supplied to the midwives in his district. This instrument held nearly one-and-a-half pint of fluid, the caoutchouc pipe was about 39 inches long, and furnished at its end with a firm nozzle of elastic gum about 4 inches long. Then the patient was made to rest upon her elbows and knees,

so that the anus became the highest point of the intestinal canal. [He lays great stress upon this position.] About half a gallon of water was injected in this way, the nozzle of the irrigator being passed as far as possible into the rectum. The patient bore the operation very well, and her pain was not much increased by it. Bubbles of gas soon escaped through the thin layer of water left in the cylinder, and the injection was then discontinued. No fluid escaped from the anus as long as she maintained this position. A large quantity of hardened fæces came away with the fluid when the bowels acted, which they did almost immediately, and the collapse and feelings of syncope passed off, with the administration of a single glass of wine. There had been no return of the obstruction. Dr. Wilbrand justly observes that a water-can and an India-rubber or elastic tube, might at any time, and almost anywhere, be converted into an irrigator of this sort.

W. BATHURST WOODMAN, M.D.

GUTTMANN ON PARALYSIS OF THE VAGUS IN MAN.—Dr. Guttman (*Virchow's Archiv*, vol. lix. part 1), reports the following case. A boy, six years of age, was supposed to have suffered early in May, 1873, from a very slight attack of diphtheria. In the course of a fortnight, recovery was apparently complete. But a week subsequently a series of nervous disturbances were noticed, on account of which the patient was brought to the hospital.

Dr. Guttman then found the head turned to the right; active flexion and rotation to the left were almost impossible, and, after passive execution of these movements, the head rapidly returned to its previous position. Nothing could be detected in the cervical region to account for this evident paralysis of the left sterno-cleido-mastoid. The electrical irritability of this muscle was somewhat impaired. There was slight weakness of both lower extremities in walking, and vacillation when the eyes were closed. The voice had a very marked twang, due to a complete immobility of both arches of the velum palati and of the uvula during phonation. Speech, also, had become somewhat heavy within the last few days. Swallowing was slightly difficult, but the ingesta were not forced through the nose. The muscles of the pharynx acted powerfully. There was nothing abnormal in the larynx.

The most important feature of the case was a very intense and peculiar dyspnœa. The frequency of the respiratory acts in one minute was twelve. Each inspiratory act was unusually deep, and was performed by the increased activity of all accessory muscles of respiration. The thorax was greatly distended, only the lower intercostal spaces in the axillary line and the epigastrium were drawn in during each inspiration; a phenomenon which, Guttman states, is very frequent in chronic dyspnœa, and most marked in emphysema of the lungs. Expiration was longer than normal, but was performed by the elasticity of the lungs exclusively. There was no cyanosis, and physical examination gave absolutely negative results. Pulse 120, regular. Temperature normal. His appetite was pretty good; the bowels were regular. The patient complained only of dyspnœa. Death took place on the day on which he applied at the hospital, at 6 P.M. A necropsy was not permitted.

From the resemblance which the dyspnœa just described bears to the one observed after section of both vagi, and from the absence of physical signs,

* In the notice of Dr. Mosler's paper at page 747 of the LONDON MEDICAL RECORD for Nov. 26, 1873, Dr. Sansom's name is printed as Simpson, by mistake.

Guttmann concludes that this dyspnoea was due to paralysis of the vagus, because nervous disturbances of various kinds frequently follow an attack of diphtheria.

MOSLER ON THE LOCAL TREATMENT OF CAVITIES IN THE LUNGS.—In order to prevent the dangerous consequences which are supposed to arise from the retention of pus in the lungs, Mosler (*Berliner Klinische Wochenschrift*, no. 43, 1873) injected disinfecting fluid through the thoracic walls in two cases where cavities could be distinctly recognised. The operation was not followed by pain or other constitutional disturbances, and the results were favourable.

In a third case of phthisis of long standing, complicated with amyloid degeneration of the kidneys, a cavity was opened through the thoracic walls by means of an incision in order to allow the free escape of the purulent contents. A tube was left in the cavity, and attached to the chest by means of strips of adhesive plaster. The evening after the operation the temperature was 37·8° Cent. (100·4° Fahr.); pulse, 84; respiration, 36. A large quantity of purulent substance escaped through the tube, the cough gradually diminished, and the constitutional symptoms also begun to ameliorate as much as could reasonably be expected where the disease had gone so far. Inhalations through the tube of carbolic acid and iodine, greatly diminished the quantity of the secretion, which now became good pus. The kidney-disease, however, made rapid strides, and the case proved fatal a few months after the operation. On *post mortem* examination, it was found that granulations had begun to spring up from the walls of the cavity. I. B. BERKART, M.D.

APPLIED PHARMACY.

GROVES ON NEPAUL ACONITE AND THE ACONITINES.—The announcement of the author at the Liverpool meeting of the British Pharmaceutical Conference in 1870 (*Pharm. Journ.*, [3], i. 433) that he had succeeded in obtaining a second aconite alkaloid in a crystalline form from Nepaul aconite does not appear to have met with universal acceptance on the continent. M. Duquesnel, whose memoir *De l'Aconitine cristallisée et des Préparations d'Aconit* gained for him the Barbier prize of the French Academy, in summing up the results of his research, states that the activity of *Aconitum ferox* is not due to its containing a more energetic principle than aconitine, but to its containing a greater quantity of that principle. M. Patrouillard, the author of a recent exhaustive treatise *De l'Aconit et de l'Aconitine*, admits the distinction between the German or true aconitine, and the English or pseudoaconitine, but endeavours to show that these substances are more or less impure varieties of a single pure aconitine. Professor Fluckiger, on the other hand, recognised in some crystals that had been sent to him, all the characteristics of the pseudoaconitine of Von Schroff, of Vienna. In order to

produce conviction by presenting to competent experimenters specimens of the different alkaloids for comparison, Mr. Groves obtained a further supply of Nepaul aconite, and the result of his operations, the details of which are given in a paper read before the British Pharmaceutical Conference at Bradford (*Pharm. Journ.* [3] iv. 293), but are too long for insertion here, is that he has offered to place an ounce and a half of crystallised pseudoaconitine at the disposal of the Conference for further investigation to determine its atomic weight. Mr. Groves used the term 'Nepaul aconite' in preference to *Aconitum ferox*, because M. Patrouillard has raised some doubt as to the original statement of Wallich that *Aconitum ferox* is the sole source of bikh.

The remainder of the paper is devoted to a report upon some of the characteristics of the aconite alkaloids, those reported upon being crystallised aconitine and amorphous aconitine derived from *Aconitum Napellus*; and Morson's aconitine, pseudoaconitine in crystals, amorphous pseudoaconitine, and napellin derived from Nepaul aconite. When boiled in a test-tube with a small quantity of water, Morson's (amorphous) aconitine and the amorphous pseudoaconitine were fused and stuck to the glass; napellin also was readily fusible; but the others were not. Heated destructively in the bottom of a test-tube, all these preparations gave off acid vapours of the same odour as the pyroligneous acid used for curing hams. The vapours given off by quinine and strychnine under the same circumstances were alkaline. The aconitines heated with hydrate of soda gave off ammonia. In solutions of ammonia containing respectively 1½ per cent. of alkali and half that quantity, they were soluble in the following proportions. No deduction was made for the nitric acid in the nitrate, the salt being anhydrous and the nitric acid was set against the hygroscopic water of the other samples.

| One grain of alkaloid soluble in | Stronger Ammonia Water. | Weaker Ammonia Water. |
|-------------------------------------|-------------------------|-----------------------|
| Crystallised Nitrate of Aconitine . | 520 | 589 |
| Amorphous Aconitine . . . | 1,005 | 860 |
| Crystallised Pseudoaconitine . . . | 2,674 | 2,500 |
| Amorphous Pseudoaconitine . . . | 1,489 | 1,372 |
| Morson's Aconitine . . . | 881 | 684 |

This shows that crystallised aconitine is by far the most soluble of the series, and it alone is more soluble in the stronger than in the weaker ammonia water. Amorphous aconitine approaches in character the pseudoaconitines, being less soluble than aconitine, and more soluble in the weaker than in the stronger ammonia water. The much smaller solubility of crystallised pseudoaconitine distinguishes it at once from the aconitines, with which it has been persistently confounded. It is also slightly more soluble in the stronger ammonia water. The action of heat on these ammoniacal solutions was equally characteristic, and the difference in their degree of permanence was very marked. Crystallised aconitine, after twenty hours, was much diminished in strength, and ten hours later the alkaloid had entirely disappeared. Amorphous aconitine was more stable, and crystallised and amorphous pseudoaconitine still more so. Morson's aconitine also very slowly decomposed, approaching in permanency the pseudoaconitines. Indeed, Mr. Groves is disposed to think that it is

pseudaconitine with its apparent solubility increased by a large admixture of napellin. The author knows of no colour-reactions of these alkaloids. Boiled with solution of ammonium chloride they all, especially the pseudaconitines, liberate ammonia. Of the aconitines the crystallisable salts are numerous, but the salts of pseudaconitine are too soluble both in water and in spirit, to allow crystallisation. They arrive at the state of syrup, and pass from that to a transparent glass, which, when it becomes absolutely dry, cracks up into scales. The crystals of pseudaconitine are entirely dissimilar to those of aconitine. Mr. Groves thinks it probable that there are two series of allied alkaloids, the one furnished by *Aconitum Napellus*, the other by *Aconitum ferox*, or some other Indian aconite. Each species seems to yield its crystallised aconitine, its amorphous aconitine, and its napellin. Should his conjecture prove correct, he suggests that the prefix 'pseud' should be replaced by 'ind.'

ALLEN ON THE ANALYSIS OF TEA.—In a paper read before the British Pharmaceutical Conference, Mr. A. H. Allen of Sheffield criticises the methods usually followed in the examination of tea for the purpose of detection of adulteration (*Pharmaceutical Journal*, iv. 331). The three principal constituents of tea are tannin, gum and woody fibre, with smaller quantities of some albuminoid body, theine, colouring matters, chlorophyll, essential oil, etc. The proportions found by different analysts vary very much, the difference evidently depending upon the methods of determination employed. Mr. Allen finds that the estimations of tannin present the greatest variations, and in many cases are manifestly wrong. Hassall directs to exhaust a weighed quantity of dried tea with hot water, dry and weigh the residue as 'woody fibre'; to precipitate the infusion with alcohol and so obtain the percentage of gum; and then to estimate the tannin by difference. By this method other matters are reckoned as tannin, and too high a result obtained. The same may be said of an alternative method of the same author, to precipitate the tannin by a solution of gelatine, and weigh the precipitate, 100 grains of it being taken as equal to 40 of tannin, since the precipitate of leather carries down with it a large and variable quantity of colouring matter. The author has found a modification of the latter process, in which the tannin is volumetrically estimated by means of a standard solution of gelatine to give very concordant results. Twenty grains of tea are boiled for half an hour in three or four ounces of distilled water, the solution drained off, and the leaves boiled again in a little more water, the two solutions mixed and made up to a measured quantity. One tenth of this liquid (equal to two grains of tea) is placed in a beaker with an equal bulk of water and a standard solution of gelatine added, about five grains at a time, with repeated stirring. When the precipitation appears to have terminated, a small quantity is filtered into a test-tube and tested with a little solution of gelatine separately. If a further precipitation takes place it must be returned to the bulk and more solution having been added, the operation repeated until no further precipitate is formed. It is then tested with solution of tannin to insure that the limit has not been passed. The operation is then repeated on half the original solution (ten grains of tea), the results obtained in the preliminary test enabling the operator to add nearly the required amount of gelatine solution at once. The results

may be further corroborated by testing the remaining portion (equal to eight grains). The standard solution of gelatine the author makes by dissolving forty grains of Nelson's gelatine in 7,000 fluid grains (sixteen ounces) of distilled water and adding fifteen grains of powdered alum to facilitate the subsidence of the precipitate. The strength of this solution may be tested by means of a standard solution of pure tannin. By the above process the author found in black tea of good quality 12·5 per cent. of tannin, and in green tea about 19 per cent., figures approaching closely those given by Mulder, viz., black, 12·88; green, 17·80. He considers the estimation of the tannin of the first importance, since if it reaches the normal amount all question of adulteration by exhausted leaves is at an end, and that the only fallacy in such a conclusion would be caused by an admixture of catechu or sloe leaves.

The 'insoluble' matter Mr. Allen estimates by boiling the tea in water as long as the water is coloured by its straining, and drying the residue. With good teas the results obtained have been very constant, varying from 50·5 per cent. to 51·2 per cent. in green teas and from 58·7 to 60·8 per cent. in black. Any large excess of this average would imply the probability of a mixture of exhausted leaves.

To estimate the 'gum,' the solution strained from the 'insoluble matter' is evaporated to a syrup, treated with redistilled (methyated) spirit, the precipitate of gum washed with spirit, dried, and weighed.

The percentage of gum, insoluble matter, and tannin, will enable an analyst to form a very accurate opinion as to the presence or absence of exhausted leaves. To illustrate this, the following table is given in which the results obtained by the foregoing methods from a sample of very superior black tea are placed in juxtaposition with the numbers obtained after some of the same sample had been infused in the usual manner in the teapot, no second addition of water being made, and the leaves redried.

| | Original Tea. | Exhausted Tea. |
|--------------------------|---------------|----------------|
| Moisture | 9·2 | 11·1 |
| Insoluble Matter | 58·7 | 87·5 |
| Gum | 10·5 | 3·8 |
| Tannin (by Gelatine) . . | 15·2 | 3·3 |

From this it will be seen that such an exhaustion of the leaves results in the increase of the relative proportion of insoluble matter by nearly 30 per cent., whilst the gum and tannin are much reduced in amount. Generally the exhausted leaves are redried and made up with gum, which dressing gives them a peculiar glossy appearance, and is detected upon analysis through excess of gum.

The original paper is accompanied by details of the results obtained upon the analyses of numerous specimens of tea, which have been examined by Mr. Allen in his capacity of analyst for the borough of Sheffield.

WANKLYN ON ANALYSIS OF TEA.—Mr. Wanklyn calls attention to the fact that the ash of genuine tea-leaves contains a considerable proportion of oxide of iron, amounting, according to Zoller, to 4·38 per cent. of the ash (*Chemical News*, xxviii. 186). From this it is evident that the mere qualitative detection of oxide of iron in the ash of tea is no valid proof of adulteration, unless it sensibly exceed 4 per cent. of

the whole. Mr. Wanklyn also calls attention to the importance of investigating the ash of samples of tea. Several samples examined by himself yielded from 5·30 to 5·99 per cent. of ash, and an average of 5·75 per cent., closely approaching the 5·63 per cent. found by Zoller. These determinations were with air-dried tea; absolutely dry tea yields 5·92 per cent. This percentage and the relative proportions of its soluble and insoluble in water differ considerably from that of other leaves, as will be seen by the following results made last August by the author.

| | PERCENTAGE OF ASH FROM DRIED LEAVES. | | |
|----------------------|--------------------------------------|-------------------|---------------------|
| | Total. | Soluble in Water. | Insoluble in Water. |
| Common Tea . . . | 5·92 | 3·55 | 2·37 |
| Paraguay Tea . . . | 6·28 | 4·22 | 2·06 |
| Beech | 4·52 | 2·00 | 2·52 |
| Bramble | 4·53 | 1·84 | 2·69 |
| Hawthorn | 8·05 | 3·78 | 4·27 |
| Raspberry | 7·84 | 1·72 | 6·12 |
| Willow | 9·34 | 4·16 | 5·18 |
| Plum | 9·90 | 5·66 | 4·24 |
| Elder | 10·67 | 3·19 | 7·48 |
| Gooseberry | 13·50 | 7·83 | 5·67 |

From this table it appears that the ash of Paraguay tea is the only ash that could not by its total percentage be readily distinguished from tea-ash; it, however, differs from the latter by containing a higher proportion of soluble matter. In estimating the ash, Mr. Wanklyn burns two grammes of dried leaves in a small platinum dish, and when the resulting ash has become grey, the dish is allowed to cool, and is then weighed with its contents. The ash is next boiled with a little water, the solution filtered and evaporated to dryness, and the residue ignited, cooled, and weighed. These operations give the 'total ash' and the 'soluble ash.' The 'insoluble ash' is estimated by difference. Any sand that may be present remains in the insoluble portion, and does not dissolve when that is treated with hydrochloric acid, although the portion of real tea-ash insoluble in water is almost entirely soluble in hydrochloric acid.

Mr. Wanklyn also points out that the composition of the ash of normal tea-leaves differs considerably from that of spent tea-leaves. The latter is far less rich in alkalies and much less soluble. Zoller's analysis of the two kinds are represented as follows.

| | Unused Leaves. | Spent Leaves. |
|---------------------------------|----------------|---------------|
| Potash | 39·22 | 7·34 |
| Soda | 0·65 | 0·69 |
| Magnesia | 6·47 | 11·45 |
| Lime | 4·24 | 10·76 |
| Oxide of Iron | 4·38 | 9·53 |
| Protoxide of Magnesia | 1·03 | 1·97 |
| Phosphoric Acid | 14·55 | 25·41 |
| Sulphuric Acid | Trace | Trace |
| Chlorine | 0·81 | Trace |
| Silica | 4·35 | 7·57 |
| Carbonic Acid | 24·30 | 25·28 |
| | 100·00 | 100·00 |

HOWIE ON THE EXAMINATION OF POWDERED RHUBARB, AROMATIC CHALK POWDER, AND MUSTARD.—The author, in a paper read before the British Pharmaceutical Conference (*Pharm. Journ.* [3] iv. 354) describes a test for the presence of turmeric in the above substances, which is based upon the free solubility in chloroform of curcumine compared with that of the other colouring matters. The test may also be used to distinguish the finer qualities of East Indian rhubarb from inferior or European varieties. The test for rhubarb consists in placing about five grains of the powder on a small piece of blotting paper, in a small compact heap, flattened at the top, and dropping chloroform cautiously on to the centre of the powder, until the chloroform, slowly percolating to the circumference and carrying with it any soluble matter, extends nearly an inch from the powder. When the paper is dried, it will be found that a yellow stain of varying intensity has been left round the powder. With really fine bright-coloured East Indian rhubarb the stain is scarcely perceptible, but cheaper and darker samples may yield a brilliant yellow, whilst the finest bright-coloured English powder will give a yellow stain as deep as, or in most cases deeper than, the darkest East Indian. If turmeric be present in any quantity, this also yields a brilliant yellow stain. To distinguish between the stain from inferior rhubarb and that from turmeric, place a little powdered borax, or a drop of a saturated solution of boracic acid, on the deepest part of the stain, and then with a glass rod deposit a single drop of hydrochloric acid on the borax. In a few seconds, if the stain be from turmeric, a distinct red is produced, which is changed to black or greenish-black by solution of potash. No change except a slight bleaching takes place if the yellow be due to rhubarb colours only. Solution of potash also changes instantly the yellow turmeric stain to a more or less brown tint, whilst a pure rhubarb stain gives a reddish purple colour. By this means, the author states the presence of 0·05 per cent. of turmeric can be detected. As turmeric often carries wheaten flour or farina in its train, its presence in rhubarb should be looked upon with suspicion.

A powder offered as East Indian rhubarb, of pale brilliant colour, having the usual characteristics of that variety, should give but an exceedingly pale tint. Should a deep yellow be given, the author would suspect English or French contamination. An East Indian powder of dark hue, however, may give almost as deep a colour as the English, and still be genuine, though he would then judge it to be the product of unpicked roots, trimmings, or even worm-eaten pieces, according to the depth of tint. Some specimens of Turkey rhubarb yielded similar results.

The cause of this varying colour yielded by different rhubarbs is somewhat obscure. Chloroform seems to dissolve out the coloured resinous principles erythretine, phaeoretine, and aporetine, while the crystalline principles, chrysophanic acid and emodine, are left behind. This may be shown by percolating East Indian rhubarb with ether after chloroform; upon the evaporation of the ether crystals of chrysophanic acid are left. It is noteworthy that English and French rhubarbs treated thus yield no such crystals, the residue being a minute quantity of pale brown gummy extractive; though from all varieties distinct brownish acicular crystals, probably emodine, are obtained. The author suggests that chrysophanic

acid, which is recognised as the chief principle of rhubarb, by continued exposure to atmospheric influences, absorbs oxygen, and is converted into the above-mentioned resins, which indeed some have not accepted as distinct principles, but assert to be impure chrysophanic acid. It would thus become soluble in chloroform.

In the same manner the substitution of turmeric for saffron in aromatic chalk powder may be detected by chloroform, since crocine, the colouring matter of saffron, is not soluble in it. The test may also be used for the detection of turmeric in mustard condiment.

B. H. PAUL, Ph.D.

DERMATOLOGY.

FOOT ON CHROMIDROSIS.—Dr. A. W. Foot (*Irish Hospital Gazette*, Dec. 1, 1873) relates a case occurring in a girl of seventeen. She was studious, excitable, and subject to severe nervous headaches. After three weeks of headache, a blue stain appeared on the forehead, which slowly returned when wiped off, and had all the characters of coloured sweat. It frequently appeared on the whole face. There seems, in this case, to have been no possibility of deception. The blue exudation was particularly excited by local warmth, by stooping, and by blushing. The veins of the forehead were somewhat enlarged, and the eyes occasionally oedematous. While under observation headaches frequently returned, appetite was bad, and on one occasion the patient walked in her sleep. The catamenia were only occasionally suppressed, but were generally tardy. The only other part on which the blue sweat appeared was the back of one hand, and this on a single occasion.

The internal treatment pursued was 'first bromide of potassium, on the supposition of 'congestion of the brain from overwork;' then hydrocyanic acid and calumba; and lastly arsenic; but none of these drugs appeared to have any effect on the blue sweat. Locally lead and zinc ointment was applied without benefit, and afterwards flexible collodion (made with castor-oil and Canada balsam) as a direct astringent. But this also was of no service; for, though it prevented the exudation where it was applied, the region of blue discoloration spread beyond the limits of the collodion. The headaches first appeared in December, 1869, the chromidrosis three weeks later. By June in the following year, menstruation became regular under aloes and other appropriate treatment, and from that time the blue sweat appeared less frequently, while the headaches became rarer and less severe. Before the end of 1870, the peculiar exudation had appeared for the last time.

The only local treatment which Dr. Foot thinks was of any value was a lotion of four drachms of hyposulphite of soda in four ounces of water, applied as constantly as possible. This was on the hypothesis that the blue colour depended on the formation of indigo-blue by oxydation of indican. The urine was examined for the latter compound, but without result.

[Similar cases have been recorded by Sir Benjamin Brodie (*Med. Chir. Tr.*, vol. xxviii.), and by many other trustworthy authorities; but their existence has been doubted or denied by Roger, Hebra, and Mr. Wilson. In a case recorded by Dr. Kollmann, of Würzburg (*Neumann, Hautkrankheiten*,

p. 65), the sweat appeared first uncoloured, and gradually acquired a deeper blue tint. Chemical analysis showed the presence of phosphorus and iron. The pigment was insoluble in water, and the colour was not discharged by alkalies. The patient was a man aged forty, of very weak and nervous temperament. The present case, in addition to those published by Dr. Foot in the *Dublin Quarterly Journal* for 1868, forms a satisfactory proof of the genuineness of this curious affection.—*Rep.*]

P. H. PYE-SMITH, M.D.

VEIEL ON THE TREATMENT OF LUPUS ERYTHEMATOSUS.—Dr. Theodore Veiel, in an inaugural dissertation (Tübingen, 1872), gives a record of all the cases of lupus erythematosus which have been treated at the institution of his father and brother at Canstatt during the past seventeen years, with a good description of its natural history, and a detailed account of the various forms of treatment there employed against it. Up to the time of its publication, the best results were obtained by chloride of zinc in solution in an equal quantity of alcohol, used as follows. A blistering plaster is first applied to the whole affected part. The epidermal covering, which forms a thick and opaque coat, is then removed, revealing the deep-red velvety papillæ, sharply defined by contrast with the firmer and paler healthy portions. The diseased parts are then painted with the solution. The pain is considerable. The yellowish-white varnish-like crust which forms is removed by poultices on the third or fourth day, and the cauterised parts are found covered with epidermis, offering in this respect a marked contrast to lupus vulgaris, which exhibits, under similar treatment, a surface of exuberant granulations, which cicatrises much more slowly. Points which still remain open quickly heal under the use of the alcoholic solution of chloride of zinc, diluted one-third with water. Cauterisation in this way is repeated until the cure is complete. Although the scars are larger than after spontaneous cicatrization, they are not in the majority of cases disfiguring.

In an article on the treatment of lupus and lupus erythematosus (*Archiv für Dermatologie und Syphilis*, vol. v. part 2, and *Boston Medical and Surgical Journal*), Dr. Ernst Veiel gives a detailed account of the later method employed at the Cannstatt Skin Hospital, which is a combination of the chloride of zinc cauterisation above described, and Volkmann's method of scarification. For this purpose, and to prevent the great loss of blood which often follows the use of the customary single lancet, 150 to 200 grammes generally flowing when the operation is prolonged for the necessary half-hour, in ordinary cases affecting the face, he has designed a set of blades placed side by side, and inserted in a common handle, by which six punctures are made simultaneously. The duration of the operation is reduced to five or ten minutes, and thus more immediate attention may be given to controlling, by pressure, the hæmorrhage. On this account, too, the necessity for the use of anæsthetics during the operation is diminished; although, as the author says, the principal effect upon the patient is not produced by the scarification and cauterisation, but by the persistent pain which often lasts eighteen or twenty-four hours, and then 'the danger which is a part of every administration of chloroform is out of all proportion to the amount of pain to be endured.'

Directly after the puncturing, the parts are cau-

terised with the alcoholic solution of chloride of zinc. Superficial suppuration follows, and crusts form, which fall off in from six to ten days, after which the puncturing and scarification are again performed. This is repeated until a smooth and uniform cicatrix is formed, which subsequently becomes white. Generally, five to eight times are sufficient for a perfect cure. Relapses, however, are not wanting, even with this treatment, manifesting themselves as red points in the cicatrix, which by confluence are converted into true lupus spots; but these are easily nipped in the bud by a repetition of the treatment.

In ordinary lupus, Dr. Veiel thinks this method effects a material reduction in the time of cure. A longer period, however, between the operations is required, inasmuch as ulceration often occurs in the parts most deeply cauterised, which must be healed by repeated applications of the diluted solution of chloride of zinc before another scarification.

ELECTRO-THERAPEUTICS.

ONIMUS ON DIFFERENCES IN THE PHYSIOLOGICAL ACTION OF INDUCED CURRENTS ACCORDING TO THE NATURE OF THE WIRE.—M. Onimus (*Comptes Rendus*, Dec. 1) procured three similar induction coils, with wires of copper, lead, and German silver, respectively. The diameter was the same; the length, 210 mètres (230 yards) for each of the wires. All the coils were acted on in the same way by the induced current.

On the nerves and muscles of a healthy man, the effects of shock are different according to the nature of the metal; and it may be said generally that, when the wire of the coil is of a metal which conducts electricity badly, the contraction is greater, and the impression on the cutaneous nerves more vivid, than when the wire is of good conducting metal (copper, for example).

These effects are the more marked, the greater the external resistance. Thus, on passing the current through alcoholised water, and diminishing it to a minimum, at which the muscular contractions did not occur with the current produced in copper wire, it was possible still to obtain contractions, other conditions being the same, with a coil of German silver wire. The lead, being a worse conductor than copper, but a better than German silver, gave intermediate effects.

In superficial muscles, the difference between the currents of the copper coil and those of the German silver, is still more pronounced; and it increases, the thicker the epidermis, and the deeper the muscle. The impression from the lead or German silver wire is deeper; it is less irradiated on the superficial nerves of the skin. On the sensitive nerves, situated in the substance of the tissues, the excitation is perhaps more vivid than that from the copper wire, but the pain is less acute and shooting. M. Onimus concludes from the facts described, that the induced current in badly conducting wires has a greater tension than that in good conductors.

He further obtained tracings of the muscular contractions produced by the different coils. These distinctly indicate the more energetic action of the German silver coil. Employing the minimum current, and the conditions being exactly similar, the curve from each contraction is much higher for the German silver, than for the copper coil. Moreover,

with the German silver coil the contractions are regular and equal, and all show the double shock, due to closing and opening. The tracing from the copper coil presents more irregular contractions; several of them are very slight, and it is rare that the double shock is perceptible. These differences are more marked, the thicker the epidermis through which one operates on the muscle. If the rheophores be inserted in the muscle of which a tracing is to be had, the difference still appears, but is very slight. In this case, the tracing which gives the contraction for the copper coil, also shows the two shocks.

On further study of these tracings, it appears that the shock produced from lead or German silver wire has a slightly longer duration than that from copper wire. These experiments also show that the tension is greater in currents induced in lead or German silver wires. It is, at the same time, remarked that these differences, from the physiological point of view, connect themselves with those between the extra-current and the induced current, properly so called. If the currents from wires of lead or German silver have a much greater tension than those from copper, they have, on the other hand, an inferior quantity, owing to their bad conductivity. Thus, in experimenting with the same coils, while the current from the copper gave, in the galvanometer, a deflection of 20 to 25 degrees, the current from the lead gave $1\frac{1}{2}$ degrees, and that from German silver only half a degree. M. Onimus suggests that, in view of the facts above stated, German silver might with advantage be used in electro-medical apparatus; (lead is less suitable for making a fine wire).

ALEX. B. MACDOWALL.

AMUSSAT ON THE TREATMENT OF SERO-SANGUINEOUS CYSTS OF THE NECK BY ELECTRICITY. Dr. Amussat, jun. (*La France Médicale*, Nov. 1873) has described two cases of this kind which he treated by the galvanic cautery, and by galvano-puncture. Such cysts may become developed in the thyroid body, the lymphatic glands, and the connective tissue of the neck. If not very large, they are simply disfiguring; but, if they grow much, they interfere with deglutition and respiration, compel the patients to carry the head either laterally or forward, and generally determine habitual congestion by compressing the vessels of this region. They contain various substances, but mostly simple serum, or serum mixed with blood, or pure blood. One of Amussat's cases was that of a man, aged sixty-nine, who had a tumour on the right side of the neck; it was fluctuating, not tender, had not given rise to discoloration of the skin, and extended from the angle of the lower jaw to the sternum. An exploratory puncture with a trocar brought away a quantity of a chocolate-coloured liquid. The cyst was allowed to fill again, and then the galvanic cautery was used in the following manner. The tumour was punctured above the internal extremity of the collar-bone with a long explorative trocar, which was directed obliquely upwards and backwards, so that the point came out behind the angle of the lower jaw; the stilet was then taken out, and a platinum wire substituted for it, the extremities of which projected beyond its entrance and exit for about ten centimètres each way. The end of the cannula of the trocar was then brought back into the interior of the cyst, and the contents were evacuated, after which it was withdrawn. The two ends of the wire were then seized with clamps connected with a galvanic cautery

battery; the wire was rendered red hot, and the interior of the cyst cauterised, care being taken to bend the wire laterally so as to act upon different portions of the internal wall of the sac. Poultices were then used, and there was neither local nor general reaction. About a month afterwards (!) the platinum wire was withdrawn, and the opening sores dressed with a cerate and cotton-wool. Five months afterwards these small sores had completely healed, and the patient was well. He was seen again six months later, when the only indications left of the tumour were two small cicatrices at the points of entrance and exit of the wire.

The second case was that of a lady, aged twenty-four, who had on the left side of the neck a tumour of the size of a nut, just above the carotid artery. Iodine had been used externally without success. Amussat introduced two fine steel needles connected with the poles of a small Bunsen's battery, and allowed the current to pass through it for five minutes. A somewhat larger battery was then used, and altogether forty-five applications were made, which were followed by external use of the tincture of iodine, and the tumour ultimately disappeared. Amussat does not think that the tincture of iodine had much to do with the cure, as it had already been used before without result, and the tumour was considerably diminished by the galvano-puncture alone before the iodine was again resorted to. He also says that, if he were again called upon to use the galvanic cautery in cases like the one just mentioned, he would take the platinum wire out immediately after the operation, and thereby shorten the duration of the treatment.

JULIUS ALTHAUS, M.D.

REVIEW.

Lectures on Madness. By EDGAR SHEPPARD, M.D.
London: Churchills. 1873.

Dr. Sheppard publishes seven lectures written for the students of King's College. In the first lecture he considers insanity generally, its prevalence and causes, predisposing and exciting. 'A great many seemingly small and trivial circumstances go towards conditioning a disturbance which ultimately eventuates in disease.' He lays great stress on the study of the natures of the young, their parental antecedents, proclivity and temperaments. A nervous child should be placed in a strong-minded family; that is, with those who have the will in complete domination, never allowing themselves to be betrayed into doubt or vacillation. Insanity is slightly more common in males than in females, in the agricultural more than in town populations. As to the exciting causes, we obtain very uncertain information, cause and effect being often confounded. Many so-called moral causes have a physical cause in the background, as drink or starvation. The most frequent of physical causes is intemperance, and this is often a symptom of an inherited neurosis. The importance of early treatment in insanity cannot well be over-estimated, but the difficulty attending it is immense, as friends will not believe in the danger that is impending.

In his second lecture, Dr. Sheppard notices briefly some of the appearances found in the brains of the insane; and after some remarks on classification, especially that of Pinel, viz.: mania, melancholia, dementia and idiocy, to which he adds general paralysis, he passes to the subject of melancholia, which he describes

as simple, acute, and *melancholia attonita* or *mélancolie avec stupeur*. He strongly advocates in this disorder the use of the Turkish bath, as well as of bathing generally. He prefers chloral to opium. When food is refused it must be given by artificial feeding, and Dr. Sheppard prefers the stomach-pump to any other mode of feeding. 'As long as a man has got a mouth, and it can be opened (and I have never seen one that could not be opened), I shall continue to regard it as the legitimate highway to the stomach.' Great precautions are to be observed here with regard to suicide.

The third lecture is occupied with the subject of mania; and a case of acute delirious mania occurring in a girl of nineteen is related, in which packing in the wet sheet was attended with the best results, and the mania at once subsided. If it do not subside, but alternate with melancholic symptoms and refusal of food, an asylum will be necessary. The diagnosis is important; it must not be confounded with other forms of delirium. Acute mania is illustrated by the case of a gentleman, thirty-six years of age, a stock-broker, whose business had caused him much anxiety. Incoherent hilarity and mischief were the leading features. He had been ill for nearly two months, and removal to an asylum was recommended. He improved, but had three relapses before recovery took place, which happened in about seven months. There was no hereditary taint, no fixed delusion. To procure sleep digitalis is to be given, or chloral. Simple mania generally comes on gradually, and may pass off quickly, or may assume the form so often termed monomania. If it be recurrent, the prognosis is most unfavourable. To this variety belongs the *folie circulaire* of the French, where mania alternates with melancholia.

In the fourth lecture, Dr. Sheppard considers moral insanity. It is beyond doubt, as Esquirol pointed out, that moral alienation is the proper characteristic of mental derangement. Whatever the difficulty in detecting hallucinations or delusions, there is no exception to the rule of perversion of the passions and moral affections. In cases of moral insanity it is important to inquire into the antecedents, personal and ancestral, of the individual. The insane temperament may be also of idiopathic origin. Its characteristics are vanity, restlessness, capriciousness, impulsive action with general eccentricity of thought and feeling. In *impulsive* insanity, as in *moral*, no delusions are to be found; there is impairment of volition, from perversion of feelings, desires and appetites. Where an homicidal act is committed, there is generally evidence of previous derangement. Epilepsy is often at the root of desperate attempts at homicide, an instance of which in a youth aged thirteen is recorded. Both parents were intemperate. Dr. Sheppard then briefly notices dementia, acute primary, and chronic primary. The prognosis of the first is favourable. The treatment consists of good living, quinine, wine, warm clothing, Turkish baths, and a galvanic current applied to the spinal column night and morning. The diagnosis of chronic primary dementia is not always easy; failure of memory is one symptom; it often follows apoplectic and hemiplegic attacks.

The fifth lecture contains an account of puerperal insanity, or rather insanity appearing at the puerperal season, which may be mania, melancholia or dementia, and may occur, 1. during the process of utero-gestation; 2. immediately or shortly after labour; 3. at a later period, during and from lactation. Mania

belongs to the second period; melancholia to the first and third. The rich are more often attacked than the poor, and such cases are, in the majority of instances, treated at home. The prognosis is very favourable, but depletion must be carefully avoided. Suicidal and homicidal attempts are specially to be guarded against in this form. Chloral and succus conii are the best hypnotics, or a basin of brandy and sago. In the next lecture is described general paralysis of the insane, its incubatory stage, its second or insane stage, and the third, that of complete dementia and paralysis. Dr. Sheppard considers that this disease is incurable, and that exhaustion from whatever cause, sexual excess, fast living, or intemperance, is the cause. The concluding lecture contains some remarks on idiocy and imbecility, on criminal responsibility in homicidal mania, and on feigned insanity. In conclusion, the author advocates restraint in exceptional and extreme cases.

G. FIELDING BLANDFORD, M.D.

On Relapsing Fever; with Special Relation to the Epidemic in Bradford in 1869-70. By A. RABAGLIATI, M.A., M.D., Honorary Medical Officer to the Bradford Fever Hospital.

We are at a loss to understand why this paper was published. It adds no new fact to our knowledge, nor throws any fresh light on the history, the etiology, the symptoms, or the treatment of relapsing fever. The writer professes to give an account of this fever as it appeared in Bradford in 1869-70, but he appears to us to have omitted to state many things of importance in any account of an epidemic. For instance, it is not stated when the disease commenced nor when it ended. No mention is made of the number of the cases, of the recoveries, or of the deaths. We are told that the disease chiefly affected poor people, but whether chiefly young or old, or all ages equally, is not stated. Dr. Rabagliati opens his paper with a definition of relapsing fever, differing in no important particular from the ordinary definitions; and he then proceeds to state that the disease as observed in Bradford differed in 'four rather important particulars' from Dr. Murchison's description of it. As we read the account of the Bradford epidemic, however, we do not think that it differs in any important particular from the description given by Dr. Murchison. We select for examination one of these particulars. Dr. Rabagliati says (particular 4th):— 'In the very important matter of the rash, I confidently assert that while there was no rash present in the majority of our cases, there certainly was one in the minority of them. In this particular the Bradford epidemic appears to have differed from all previously described epidemics of relapsing fever in Britain,'— a statement wholly incorrect, and which the writer could not have made if he had studied his subject with sufficient care. Reference to page 353 of Dr. Murchison's work on *Continued Fevers* will show that Dr. Murchison himself observed a rash in eight out of about 600 cases, in the recent London epidemic, and he mentions several other home authors who have made like observations. 'It appears' (says Dr. Murchison) 'to be more common in some localities than in others. Thus Tennent found a rash in 24 out of 352 cases at Glasgow.' Dr. Rabagliati himself only mentions two cases; one of them, in the opinion of the reviewer, a very doubtful one. Indeed, the impression produced in our mind from reading this paper is that, during the prevalence of the relapsing epidemic in Bradford,

typhus, enteric, and relapsing fevers existed at the same time, and that one of these diseases was occasionally taken for the other.

The only original matter in the paper is a suggestion that relapsing fever bears to typhus a relation somewhat like that which vaccinia bears to small-pox. Dr. Rabagliati bases this supposition on the ground that the few cases of typhus (number not stated) which he observed to follow relapsing fever were mild, and that they all recovered; an argument which might have force if it were shown that the majority of cases of typhus were severe except in persons who had been protected (to use a word suggested by Dr. Rabagliati's speculation) by a previous attack of relapsing fever. Unfortunately for the writer's argument, hundreds of cases of typhus are mild, and hundreds recover where there has been no protection from relapsing fever; and besides, the number of cases in which one specific disease has immediately or soon after followed another are too few to establish general propositions. We should like to know the number of cases upon which the following law is suggested: 'When the organism has already suffered from a specific disease, it is to some extent modified by it, so that it is less likely to be seriously endangered by another, and generally graver, specific disease succeeding the former, than if the more deadly attacked first.'

Dr. Rabagliati has appended to his paper several temperature charts, which would have had considerable value if the temperatures had been taken every hour or every two hours; but as they were only taken twice daily, to wit, morning and evening, it is impossible to say in how many cases the highest and lowest degrees have been obtained. We presume that the object in using a thermometer is to ascertain the maximum and minimum temperatures in the twenty-four hours, and specially the duration of the maximum temperature, which is quite impossible if only morning and evening observations be made. If the highest and lowest temperatures occurred at fixed evening and morning hours, observations made at those hours would be valuable; and even then, the important question of duration would not be ascertained. We cannot speak from actual thermometric observations of relapsing fever, but we can of enteric; and, from numerous hourly and two-hourly rectum observations, we should say generally that the maximum temperature may occur at any time between 10 A.M. and 10 P.M., and the minimum at any time between 10 P.M. and 10 A.M. We have not unfrequently observed the maximum temperature at noon, at 2 P.M., at 4 P.M., and so on. The same difference as to time has been observed in the minimum temperatures. If this be true, and our experience is confirmed by Professor Ziemssen, morning and evening observations must be of little value.

ALEX. COLLIE, M.D.

Fifth Annual Report of the Sanitary Commission of the North-Western Provinces: for 1872. Allahabad: 1873.

Although presenting no very striking features, this report is still a very satisfactory one; for it shows how we are becoming better acquainted with the habits of our fellow-subjects, and are gradually persuading them to co-operate with us in improving the sanitation of the country. The local municipalities are beginning to recognise the value of the registration of deaths, and have done something towards procur-

ing what is far more difficult to obtain, a registration of births.

Dr. Planck's report is distinguished from others of the kind, in manifesting a more minute knowledge of the habits of natives than such documents often show, and in the display, which he almost unconsciously makes, of the great interest which he takes in the general well-doing of the population. Work like that of Dr. Planck's is of more practical value than the dogmatical enunciation of opinions on disputed subjects, or those smart attacks on the views held by rival sanitary commissioners, of which we have had too many.

Dr. Planck points out at considerable length, how very imperfectly we have made our railway arrangements understood by natives; what difficulties third-class passengers have, first in obtaining their tickets, and afterwards in reaching their carriages. He also explains in detail, and suggests remedies for, many of the inconveniences, very serious to health, to which such passengers are subjected, and which, he believes, have hitherto prevented our railways from being used by natives at all to the extent that might have been anticipated. The Commissioner offers some remarks, though not of a very conclusive nature, on the connection which subsists unfortunately in all climates between irrigation and fever. In India, and in other countries, a too abundant supply of water, along with insufficient drainage, undoubtedly generates fever; and in Europe, for instance in Italy, irrigation has occasionally been abandoned locally on this account.

As regards epidemics of disease, the report shows very clearly how small-pox and cholera are each year influenced by season, their minimum prevalence always being in the cold weather; and how it is only occasionally—that is, once in three or four years—that they become widely epidemic. Fever, again, is not nearly so much influenced by season. Its ravages, in one form or other, last throughout the year, and epidemic fever is to be found in some districts in every year. No disease in India causes nearly so many deaths among natives. Thus in the years 1871-2, in the North-Western Provinces, fever caused seventeen times as many deaths as cholera, fourteen times as many as small-pox, and fully seven times as many as bowel-complaints. During the period included in this report, fever was on the increase in the North-Western Provinces (it is believed that there is an amendment in them in this respect in 1873), as it was in almost every part in India. Thus it is not only in the case of Lower Bengal, which has been devastated for nearly a decennial period by it, that this increased prevalence of fever is a subject demanding the full investigation of medical officers. The exact nature of the fever, or rather fevers (and many officers now run into the extreme of calling most fevers typhoid), and of the causes which produce it, are as yet imperfectly determined. The epidemic of dengue was very wide-spread and very intense. It was entirely new in the North-Western Provinces, and is believed to have been more fatal than is usually supposed.

Improved registration of deaths shows every year an increased rate of mortality in the native population. Still even the latest returns would make the average duration of human life longer in the North-Western Provinces than in England. There must, of course, be some fallacy in this, the most obvious source of which is the defective nature of the mortuary returns for children. J. MACPHERSON, M.D.

MISCELLANY.

THE YEAR'S BUSINESS IN DRUGS.—The trade of 1873, regarded especially from our readers' point of view, is characterised by features of great interest; and the trade in drugs and chemicals, as shown by the official returns, has been during the past annual period remarkably active. It will be useful if we shortly point out, statistically and otherwise, some of the most salient points in the year's business. Beginning with due alphabetical precision, we find that during 1873 the importation of alkali has given rise to a very active trade, as the amount imported was 95,336 cwts., a considerable increase as compared with the previous year. The sterling value of this importation annually is about 160,000*l.*, so that it will be seen it is a rather valuable branch of our import commerce. Another article, the import of which greatly increased last year, is Peruvian bark, the amount being 45,419 cwts. against 28,251 cwts., thus furnishing evidence as to the remarkable augmentation in the amount of this article received into the United Kingdom. The sterling value of Peruvian bark imported in 1873 reached the large sum of 445,184*l.* With regard to articles classified comprehensively in the returns as 'chemical manufactures and products, unenumerated,' we find that the value of these goods imported last year was 931,649*l.* This is a trade which does not appear to be liable to much fluctuation and vicissitude, but maintains the even tenour of its way, evenly, and without great change. Of late years the amount of the imports has not varied much, and therefore there is nothing special to comment upon in reference to them. The same remark also applies almost with equal force to another article to which we may allude—cochineal. Last year the imports amounted to 40,021 cwts. against 38,160 cwts. in the previous year, the computed value being, in 1873, 509,828*l.*, and in 1872, 494,541*l.* According to these figures there is no very noticeable increase in the importation of cochineal. When, however, we turn to the statistics representing the imports into this country of nitrate of soda we find a somewhat different state of things. The trade in this article appears to be steadily on the increase. The imports amounted last year to the large total of 2,393,204 cwts. as compared with 1,592,346 cwts. in the preceding year, thus indicating a very considerable increase in the trade of late. The value of these imports is already so great that probably they will amount in a little time, especially at the present rate of progress, to not less than 2,000,000*l.* sterling annually. Another article in which our readers are interested, and which shows material progress, is olive oil. The imports during the past year amounted to 35,145 tons against 23,996 tons in 1872; while the value in that year was 1,191,829*l.*, and 1,560,168*l.* in 1873. It will be perceived by these figures that we continue to import olive oil in greater quantities every year, and that, so active is the business generally, the aggregate value of the transactions in this commodity must be something immense. Palm oil, without increasing or decreasing materially, steadily maintains its normal position. The same remark may also be applied to the imports of saltpetre. These imports last year amounted to 331,517 cwts. against 335,672 cwts. in the previous twelve months, so that no fluctuation of any importance is apparent.

We turn next to the statistics of our export trade, and will shortly describe its chief features. As the articles are classified alphabetically, we come first to Peruvian bark, which was exported from the United Kingdom last year to the quantity of 29,289 cwts., and to the value of 344,265*l.* This is an increase over 1872.—The exports of cochineal, on the other hand, show a slight decrease, but nothing material, the amount last year being 19,980 cwts., and the value 264,219*l.* The exports of olive oil—always small—were last year somewhat greater than in 1872. The exact figures are—1873, quantity, 2,819 tons, value 138,753*l.*; 1872, 1,552 tons; and 1871, 2,660 tons. The exports of palm oil show a slight diminution in the total amount,

as does also saltpetre, the quantity exported last year being 15,103 cwts. against 29,619 cwts. in 1872. The exports of alkali, given under another head, increased last year, although, for the last few years, they have been very large. The amount exported from this to other countries in 1873 was 4,758,393 cwts. as compared with 4,453,068 cwts. in the previous year; the sterling value being, in 1873, 2,931,351*l.*, and, in 1872, 2,486,991*l.* The largest amount of this alkali, as many of our readers will be aware, goes to the United States, the quantity exported thither last year having been no less than 2,149,155 cwts. Germany takes the next largest quantity, and last year the amount exported to that country greatly increased. Next to Germany our best customer for alkali is Russia, then Holland, and then France. The manifold goods classed under the one heading of 'chemical products or preparations unenumerated' have not been exported more largely in 1873 than they have usually been of late years. In fact, there is no great fluctuation in this branch of the trade as will be seen by the following statistics of the exports in the three years referred to: 1873, 1,745,570*l.*; 1872, 1,863,634*l.*; and 1871, 1,588,763*l.* A steady total is thus maintained; and, indeed, it is gratifying to see that this business is carried on upon such sound principles that every year may be expected to bring round its accustomed amount of trade, without showing any of those extraordinary revulsions of panic which beset some sections of commerce, and which, when they unfortunately happen, cause no small inconvenience to those concerned, and disarrange the best laid plans.

Speaking generally with regard to the drug and chemical trade of the past year, there is no doubt that its main features have been satisfactory, and of such a character as to leave little cause for grumbling. Most of the articles connected with this branch of commerce, as shown in the official returns from which we have quoted, have progressed with great rapidity, and tend, in some degree, to confute the statements, or rather misstatements of those who make a great deal too much of the cry that our export commerce has of late materially diminished. The truth is that it has not increased during the last few months with that startling rapidity which astonished everybody some time ago, and which led the Prime Minister to speak so hopefully of those 'leaps and bounds' which characterised the commerce of this country. The exports and imports of drugs and chemicals generally have been equal to, in some cases more than, in 1872, that eventful year for British commercial interests, and with regard to the future there is every prospect of trade doing still better than in the past. What can we desire more?

THE WEST HADDON CASE.—Sir Robert Christison, Bart., Dr. Alfred Swaine Taylor, F.R.S., Dr. Wilks, F.R.S., and Dr. Moxon, of Guy's Hospital, have now, by their communications published in the *British Medical Journal*, shown that there is not, and never was, in their belief, a shadow of foundation for the statements of Mr. Rodgers, the chemical expert at the inquest, that a high temperature after death negatived the evidence that death had resulted from syncope due to the ascertained fatty degeneration of the heart; and that a high temperature after death justifies or leads to the conclusion that a volatile noxious substance (nature unknown), was administered immediately before death, and was the cause of death. Challenged publicly to adduce any scientific observed facts as a basis for these novel, pernicious, and unfounded assertions, Mr. Rodgers has failed to do so. Nevertheless, he must be aware that a witness who procures a verdict of 'death by poison,' from a country jury, and who finds that verdict followed by a fearful catastrophe, incurs a great moral responsibility, and owes to his country not less than to his profession, to the cause of justice and to the memory of the person inculpated, a frank statement of the grounds of his conviction. It is, of course, impossible that Mr. Rodgers should have made such statements without some ground; he has seen that they are regarded with surprise, incredulity, and indignation by the most experienced and distin-

guished members of his own class. A verdict has been recorded against Mrs. Waters by an inexperienced jury on his sworn evidence. Surely no responsible person should be willing to allow the verdict of error which has been recorded upon that evidence by the most authoritative judges to pass without explanation or defence. In shrinking from the task of justifying his sworn statements, Mr. Rodgers fails in a solemn and incumbent duty.

DR. PETER ALLEN, ST. MARY'S HOSPITAL, AND DR. J. J. PHILLIPS, OF GUY'S HOSPITAL.—The premature deaths of two distinguished members of the medical profession in London have taken place during the week. Dr. Peter Allen, aural surgeon of St. Mary's Hospital, died of typhoid fever; Dr. Phillips, assistant-physician accoucheur of Guy's Hospital, of apoplexy. Dr. Allen was in the prime of life, and had enjoyed excellent health till he was taken with this insidious fever. Some recent examinations of the basement of houses in Harley Street by Mr. Eassie, C.E., have shown the soil to be dangerously honeycombed with cesspools. Dr. Phillips was little over thirty, and stood on the threshold of a distinguished professional career, in which he was marked for success.

DR. SYMES THOMPSON, F.R.S.—A very painful impression has been produced by the conviction at a police-court during the week of a much-esteemed physician, Dr. E. Symes Thompson, for riding in a railway-carriage without first providing himself with a ticket. Dr. Thompson alleged, and alleges, hurry and pressure of time as the cause of the omission, and explains satisfactorily the circumstances which unfavourably impressed the magistrate. It should be stated that, when all the circumstances were known to the directors, they were desirous of withdrawing from the case. Dr. Symes Thompson has long been known as a man of peculiarly scrupulous character, and nice honour; and, as his many and distinguished friends believe him to be quite incapable of any kind of intentional wrong, it is contemplated to give some public expression to that opinion.

The Berlin medical papers of this week announce the sudden death of Max Schultze, the eminent professor of anatomy in the University of Bonn.

In Munich, on January 11, 12, and 13, there were 53 new cases of cholera, and 19 deaths.

ERRATUM.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 1*rs.* 4*d.*; free by post, 1*rs.* 6*d.*

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 1*rs.* 6*d.* Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, FEBRUARY 4, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BERNHARDT AND WESTPHAL ON SPINAL PARALYSIS IN CHILDREN AND IN ADULTS.*

Since J. von Heine published in 1840 his *Observations on Paralytic Conditions of the Lower Extremities and their Treatment*, a special form of paralysis in children, the subject has been well studied. Heine's own investigations led him to assert a preponderating lesion of the grey substance of the cord; and this is confirmed by Cornil, Prévost, Vulpian, Clarke, Charcot, Joffroy, and Damaschino. According to these authors, the anterior columns of the cord seem smaller, and there is an atrophy or entire disappearance of some of the groups of the largest ganglion-cells. Whether this atrophy be primary or depend on changes in the vessels, is doubtful. In 1869, Cumming published a case of 'extensive paralysis from morbid condition of the cord, probably congestion;' being the history of a man forty years old, who, after cold from sleeping in the wet, had difficulty in walking, and at last could only move the right shoulder, though sensibility was undiminished. Involuntary contractions in the extremities and pain supervened, but he gradually recovered so far as to be able to walk slowly. In 1872, Duchenne de Boulogne described the disease by the name of 'paralysie spéciale antérieure aigue de l'adulte, par atrophie des cellules antérieures de la moëlle.' The case by Dr. Bernhardt is given at full length, and well merits reading. An analysis of it shows a previously healthy man who, perhaps a little exhausted by diarrhoea, but still feeling well enough, took a violent cold. In from forty-eight to seventy-two hours a palsy of both extremities came on, without any lesion of the sensorium, without spasms or any signs of fever. In a few days the paralysis was absolute, and remained so for months, to give place afterwards to a gradual return of active movements, at first in single groups of muscles, later in others. The affected muscles rapidly lost their electrical excitability, at least for the induced current, and became wasted and extended. The sensibility of the skin remained intact; nor were the conditions of nutrition affected, for appetite, sleep, the excretions, &c., remained as usual, and, though he lay on his back for weeks, there were no bed-sores. The muscles of the eyes, tongue, head, and respiratory organs were never affected; but the only other movements of which he was capable were slight ones of the right thumb, and of the left fore-

finger and thumb, with power to roll the arm slightly inwards. At one time a gradual insinking of the interosseous spaces of the backs of both hands was noticed, especially in the right between the thumb and the index-finger, and this was next seen in the under part of both thighs. Then the thenar and hypothenar eminences became hollowed, and the skin wrinkled over them. Four weeks after the beginning of the disease, the strongest possible induced current excited only feeble contraction in the muscles of the thumb and little finger, and mere traces of contraction in the deltoid and biceps and quadratus femoris, but the constant current had very different effects.

On reviewing the symptoms, the likeness to the spinal paralysis of children is manifest; but of course it must be remembered that the reaction of a child's organism on the disease must be very different from that of an adult. It is as certain that, on the outbreak of the disease in children, fever and convulsions may be absent, as that they are generally present. Clearly, too, the atrophy of the affected limbs is not compensated in the adult as in children, by growing of the bones and joints, for the time of growth has already gone past. But in one, as in the other, there is at first a generally spread weakness, which after days or weeks localises itself in certain special muscular groups; in both classes the excitability of the affected muscles rapidly disappears, at least for the induced current; in both, the muscular atrophy causes deformities in separate limbs; and in both it is certain definite groups of muscles that are affected. In both, lesions of sensibility are absent, as also are bed-sores, and alterations in the excretions; but, whilst in adults the four extremities are nearly always affected, in children it is oftener seen to be a palsy of one limb, or of the upper extremity of one side, with the lower one of the other side. The prognosis in both classes is decidedly favourable to life; but an opinion as to the complete recovery or the severity of a particular case will depend on the *number* and *functions* of the affected groups. Perseverance in electrical treatment is the only thing to be recommended. It would seem that the pathological conditions in the two are identical, though opportunities for *post mortem* examination have been singularly rare. The French writers say that the disease in children is in the grey anterior columns of the cord, especially in the cervical and lumbar enlargements, which are the most altered, and in which the largest motor-trophic ganglion-cells are the seat of the chief changes. Duchenne, from the analogy of the symptoms, names the disease from a preserved identity in the pathological appearances. Gombault had an inspection where he found change in the anterior grey columns, and considerable atrophy of the large ganglion-cells, but only single nerve-tubes were without myelin and rich in nuclei. The muscles were beset with connective tissue, and the fibres which did remain were somewhat reduced in volume; often only empty sheaths of sarcolemma could be seen. The nerves to the muscles, and the nerve-trunks, contained isolated spots occupied by connective tissue, which had long usurped the place of nerve-tubes.

In considering the etiology, a prominent feature is the fact of taking cold. Must the muscular be considered the primary affection, and that of the grey substance in the anterior columns only consecutive, brought on by long disuse of the muscles? Apart from those discoveries which, denying a single

Observations and Investigations on the Diseases of the Central Nervous System. By Professor C. WESTPHAL, of Berlin.

atrophy of the ganglion-cells, see in the participation of the blood-vessels an indubitable sign of true inflammatory affection of the grey substance, it is difficult to conceive that certain muscles or nerves in a circumscribed limit should all at once be severely attacked, whilst others which are still more exposed to the cold air (as the neck- and face-muscles), should decidedly escape. The symptoms somewhat resemble those of acute general paralysis, but the latter lasts only a few days, death following very rapidly from implication of the respiratory organs.

With this paper should be read one in the same journal by Dr. Carl Westphal, on 'Myelitis occurring disseminated or in patches (*fleckweise*);' by which he intends to designate those diseases of the cord where the myelitic process is spread irregularly over a large extent, so that sections made at different heights show different diseased portions of white and grey substance, with here and there healthy parts intervening. This form (which is very little known, and whose etiology is obscure) is different from the one usually seen, where certain sharply defined parts (as the anterior or posterior columns, &c.) are affected continuously, it may be in their entire length. He gives two cases of varioloid, in the first of which, eleven days after the eruption and during the drying-up stage, paralysis of the bladder came on, on the twelfth day paralysis of the left, and on the thirteenth day of the right leg. There was found disseminated myelitis of the grey and white substances. In the second case, paraplegia came on a few days after the outbreak of the eruption, and here again disseminated myelitis of the grey and white substances, but especially of the latter, was found. It appears to Westphal that in some of the cases quoted by Damaschino, 'spinal paralysis of children,' a similar process has gone on in the cord as in the paralyses after acute febrile diseases in adults; and to prove this, he gives the results of two *post mortem* examinations made on children two years old, who were well marked instances of 'spinal paralysis.' Clinically, it would seem that many of the cases quoted as spinal infantile paralysis have in fact arisen at the close of well characterised febrile affections; thus, *e.g.* in Heine's first case, after convalescence from scarlatina, in his seventh case during the fever; and similar instances are given by West and Damaschino. The question arises whether these are truly 'infantile spinal palsy.' Laborde, in his work on *Paralyse Essentielle* (Paris, 1864) expresses himself very strongly against confounding such with the secondary palsies after acute febrile diseases; but he gives no good ground for it, and appears to have misunderstood Rilliet and Barthéz in some expressions which they used. Certainly, as regards the time of appearance of the paralysis after the fever, no difference between children and adults can be made out; nor again, have the intensity and duration of the fever anything to do with it; indeed it is curious how often in both the fever was mild and of short duration. Vulpius has often written on partial paralysis with atrophy of the affected muscles in adults after acute fevers; and, seeing that a similar pathological process has been found in a classical case of spinal infantile paralysis arising after an acute exanthem, by Damaschino, and by Westphal in adults after acute disease—the appearance being a diffused myelitis—there seems no ground for making any difference between the nature of the spinal complaint in children and in adults. Westphal was of opinion that the fact of the ganglion-cells participating in the lesion in the spinal

infantile complaint *might* give some ground for difference between this disease and that of adults, in whom opportunities for investigating are very rare; but an instance given by Gombault, in which he found the ganglion-cells affected, seems to prove that the pathological processes are the same in both. Westphal's paper is accompanied by two lithographic plates, showing beautifully the different amount of 'disseminated myelitis' in sections taken at different heights in the cord. T. C. SHAW, M.D.

CLINICAL SURGERY.

ON NECROSIS OF BONE. BY PROFESSOR HEINCKE, OF ERLANGEN.*

The frequency of this affection may be readily explained, according to Professor Heincke, by the fact that bone derives its blood-supply only from the vessels of the periosteum and the medulla, and that the vessels supplying the medulla first pass through bone. Any disturbance of the nutrition and of the circulation in the periosteum and marrow must thus exercise very great influence on the nutrition of bone. Necrosis would not be met with so frequently, if bone, like the soft parts, were capable of undergoing molecular degeneration. As this is not the case, many morbid processes which, in soft parts result in suppurative or granulo-fatty degeneration of the tissue-elements, lead in bone to necrosis. The anatomical differences between spongy and compact bone, such as the greater supply of anatomising blood-vessels in the former, and also the abundance and the regular distribution of the medulla, render it intelligible why necrosis occurs more frequently in the latter than in the former.

There are many causes which alter the nutrition of bone to such an extent as to give rise to necrosis.

In the first place, injuries of bone not unfrequently result in necrosis, the injured portion being killed either through separation from the rest of the bone, or through failure of the periosteum and the medulla to supply nutriment to the osseous tissue. Professor Heincke holds, however, that even completely detached osseous fragments do not always die, but that they sometimes form sound union with the callus thrown out at the seat of fracture. Severe contusion and concussion of bone without fracture cause laceration of the vessels passing from the periosteum to the bone and those supplying the marrow, and result in effusion of blood under the periosteum and sanguineous infiltration of portions of medulla. When these effusions are speedily absorbed, so that the periosteum becomes again applied to the bone and the circulation in the marrow is renewed, the bone continues to live; but when, on the other hand, the effused blood sets up suppurative, the periosteum remains detached, the medulla breaks down and is destroyed, and necrosis consequently results.

Necrosis is frequently caused by inflammation, acute or chronic, which causes persistent separation of the periosteum or degeneration of the medulla, or both these combined simultaneously. Acute osteomyelitis rarely terminates without necrosis, usually involving the greater part but never the whole of the affected bone. The whole of the diaphysis of a long bone is seldom necrosed, and it is an extremely rare

* Abstracted from *Volkmann's Sammlung Klinischer Vorträge*, no. 63.

event for both or even one of the epiphyses to die together with the shaft. Chronic inflammation resulting in necrosis frequently occurs in scrofulous, badly nourished, and anæmic children, and the exciting causes of such inflammation are, in most instances, chills and slight mechanical lesions. Constitutional syphilis often gives rise to chronic inflammation of bone and marrow; and finally, under the influence of phosphorus vapour, chronic periostitis and consequent necrosis may be produced in the jaws. Necrosis from acute inflammation may occur after injury, after a surgical operation involving a bone, after chilling, and during convalescence from continued fever or some acute exanthem. A very severe form of acute periostitis and osteo-myelitis is sometimes met with, in which several bones are simultaneously affected, the general disturbance being very great and giving rise to typhoid symptoms. This affection has some resemblance to acute rheumatism, especially as it is sometimes associated with endocarditis and pericarditis. It has been called articular typhus, osseous rheumatism, and by Roser pseudo-rheumatic inflammation of bone.

A third but not very frequent cause of necrosis is vascular plugging. In consequence of impairment or destruction of the circulation, primary coagulation may take place in the nutrient vessels of a bone; or the trunk or one of its larger branches may become plugged by an embolic clot. The latter is of rare occurrence. One case of undoubted embolism of an artery to bone after endocarditis has been recorded by Volkmann. Primary thromboses in the vessels of bone probably underlie, Professor Heincke thinks, those necroses which are sometimes observed in extremely debilitated subjects and in convalescents from typhoid. The coagulation is due to weakened heart's action and diminished blood-supply; it probably commences in the capillaries and small veins of the affected bone, and then rapidly extends on the one hand to the larger veins, and on the other to the arteries. The course of the necrosis in such a case is generally very rapid, the whole bone, or a considerable portion of it dying at once, and, in cases where death does not result, speedily becoming detached from the living parts.

The upper surface of a superficial sequestrum is usually quite smooth, and resembles the surface of a portion of macerated bone; but, in some cases of syphilitic necrosis and of necrosis of the jaws from the effects of phosphorus, the surface of the sequestrum is covered by osteophytic deposits, which in the former affections are delicate and like grains of sand, and in the latter form large rounded masses of bone. In those cases of osteophytic deposit, the death of bone has been preceded by an inflammatory process causing periostitic deposit in addition to osseous sclerosis. Putrefaction does not as a rule take place in sequestra, as the soft structures contained in the canals of bone and in the medullary centres commonly undergo purulent and caseous degeneration before the admission of air, and purulent and caseous deposits in a wound do not readily putrefy. In some conditions, however, putrefaction does extend from the ordinary secretion of a wound or ulcer to the ichorous and caseous masses filling the cavities of a portion of dead bone. This occurs most frequently in caseous sequestra, and in portions of bone detached in compound comminuted fracture. The parts immediately surrounding an unremoved sequestrum are pus and granulations; according to the amount of irritation, the sequestrum is surrounded

sometimes more by pus, at other times more by granulations. Pus does not exert any influence on dead bone, and a sequestrum may remain a long time surrounded by purulent fluid without undergoing any change. Granulations, on the other hand, cause wasting through pressure, and probably through the dissolvent action of the secreted fluid on the lime-salts of bone. The process of melting in masses of dead bone in contact with granulations unfortunately goes on so slowly, that no important results can thus be obtained. Through the gradual solution of osseous trabeculae lying between dilated pores, portions of sequestrum may wholly disappear, yet it seldom happens that any noteworthy diminution of a large sequestrum may be thus effected. Small sequestra may, under favourable circumstances, be thus destroyed by granulations, but sequestra of any considerable size cannot be removed by their action.

The proper time for the surgical removal of a sequestrum lies between the period of the complete detachment of the same from the living bone and that at which serious affections, such as Bright's disease and lardaceous degeneration of the abdominal viscera, make their appearance. The separation of a sequestrum from the living portions of bone does not, according to general experience, take a longer period than six months; hence the practical rule that, even in cases where the sequestrum is not movable, an attempt should be made to extract it if the necrosis commenced at least six months before. The author recommends that, where the sequestral capsule or case of new bone is very thick and its cavity very large, the whole of one wall of this capsule be removed. By this proceeding, the healing of the wound after extraction of the sequestrum is much accelerated.

CLINICAL MEDICINE.

ON THE TREATMENT OF DISEASES OF THE STOMACH. BY PROFESSOR W. O. LEUBE, OF JENA.*

After a few remarks on the importance of physiology in regard to diagnosis and treatment, Professor Leube said:—

The treatment of diseases of the stomach coincides in great part with the treatment of dyspepsia. (I must here expressly state, that I do not think it correct, in the present day, to separate dyspepsia from other diseases as a special disorder, and to treat it by itself. I rather understand the term as denoting only one of the aggregates of symptoms attending the most various diseases of the stomach.) In any case, dyspepsia is generally by far the most prominent of the symptoms which appear in the course of individual gastric affections—whether acute inflammation, ulcer, cancer, chronic catarrh, or simple dilatation, &c. The functional disorder is the manifestation of the structural changes; and it is the symptoms of dyspepsia which are generally first taken into consideration in the treatment of diseases of the stomach.

Dr. Leube then enumerated the symptoms indicating dyspepsia, and remarked that, however easy the diagnosis was, it was difficult in individual cases

* Extracts from a paper read before the fifth meeting of the Thuringian Medical Association at Muhlhausen. (Volkmann's *Sammlung Klinischen Vorträge*, no. 62.)

to find the right remedies. There is, he said, no specific for dyspepsia, like quinine for ague, or mercury for syphilis; each case must be analysed, to find out what form of dyspepsia is present, and what is its cause.

The two constituents of healthy gastric juice are, a free acid, and pepsin, the ferment which breaks up albuminous substances. Both of these are of equal importance in the process of digestion, and one cannot act without the other. Moreover, a certain proportion in the quantities of these constituents is necessary for effective digestion. The most favourable proportion is 1 to 4 parts of acid in 1,000 of gastric juice; but it is of less importance that the amount of pepsin should be constant. Albumen is dissolved more quickly, the richer the fluid is in pepsin; but a very small quantity of pepsin is capable of dissolving an unlimited quantity of fibrin, provided only that care be taken to ensure a constant supply of acid. The pepsin remains unchanged during the process of digestion of the albumen.

Dr. Leube then described the manner in which he proceeds in cases where he cannot otherwise arrive at a conclusion, to determine whether the dyspepsia depends on an excess or a deficiency of either of the constituents of the gastric juice.

I make the patient take, while fasting, about 25 grammes ($6\frac{1}{2}$ drachms) of Carlsbad salt, to carry downwards any contents that may be remaining in the stomach. After this, I make him eat at midday some dry cold roast veal with or without bread; and, an hour or two later, I withdraw a portion of the contents of the stomach by means of the stomach-tube, and ascertain by the smell and reaction how far the digestive process has advanced. I then filter the contents of the stomach which have been removed, and introduce into each of three flasks about 50 grammes of the filtrate, suspending in each an equally sized piece of boiled fibrin, and adding to the contents of one flask two drops of hydrochloric acid, and to those of another two drops of neutral solution of pepsin. The three flasks are then placed in a large vessel of water at a temperature of 35° to 40° Cent. (95° - 104° Fahr.). The amount of digestion which goes on in the contents of the flasks to which the acid and pepsin have been added, as compared with the flask to which nothing has been added, will show whether one or other of these materials produces a more rapid solution of the fibrin.

From the experiments which I have hitherto made, and from a consideration of what may possibly occur, I am led to the conclusion that, in most cases where there is a disturbance in the proportions of the constituents of the gastric juice, there is a deficient amount of acid.

As regards the pepsin, an abnormal increase is not, *a priori*, a very probable cause of dyspepsia, as, the amount of acid remaining the same, an increase of pepsin only accelerates digestion. And just as little can a diminished amount of pepsin have any other effect than a slight delay of the digestive process. As only the smallest quantity of pepsin is required for digestion, so long as there is a constant supply of acid, it depends only on the degree of secretion of acid whether the process of digestion is maintained.

Dr. Leube has not met with any case of dyspepsia in which the gastric contents, treated in the manner above described, dissolved fibrine rapidly, either without any addition or with the addition of pepsin; while the addition of acid caused the solution of the

fibrin within a period varying from twelve to twenty-four hours.

In such cases, then, the administration of acid is a therapeutic indication. It is not necessary to give it in a routine manner—a spoonful of an acid mixture every two hours; but the patient should take the medicine immediately before and after meals. I usually give eight drops of hydrochloric acid in half a wineglassful of water an hour after taking food, and, in some cases, repeat the dose four hours after meals, and I have always seen good results from this treatment. It is an interesting fact, that Manassëin,* in the experiments which he has performed on dogs under Hoppe's directions, has ascertained that a deficiency of acid is the cause of the disturbance of digestion both in fever and in acute anæmia. His researches have led him to the conclusion that, both in animals in a febrile state and in those in which acute anæmia has been induced by blood-letting, there is a change in the normal proportion of acid and pepsin, and that the addition of acid to the gastric juice exercises a greater influence in these than in healthy animals.

The last possible morbid quantitative change in the proportions of pepsin and acid, is an excessive formation of acid. However wide-spread may be the belief that this anomaly is of very common occurrence in diseases of the stomach, I must express my doubt, whether there are many cases in which an abnormally great formation of acid is the cause of dyspepsia. I do not deny that the vomited matters in many gastric diseases have an intensely sour smell and acid reaction; but this by no means signifies that there has really been too much acid formed for the performance of digestion. An intensely sour smell is no evidence of acid reaction. In some cases of dilatation of the stomach, the fluid which I have removed from the organ has had a disgustingly sour smell, but nevertheless its reaction has been neutral. Moreover, even when the contents of the stomach have a distinct acid reaction, the question is not yet answered whether there is really too much acid for digestion, as long as we do not know what the acid is which produces the reaction; and, again, there is a very marked difference in the results which the addition of one or another acid to pepsine produces on the ingesta. It has long been known that, in cases of morbid fermentation in the stomach, sometimes lactic acid, sometimes butyric acid, sometimes even acetic acid, may be present, and render the gastric contents strongly acid. Nevertheless, none of these newly formed acids, perhaps with the exception of lactic acid, can effectively replace the hydrochloric acid in the gastric juice. For, even though these acids, like all others, are capable of forming digestive components with pepsin, yet the combination always has a very feeble digestive power; and regarding acetic acid especially, it has been ascertained that ten times as much of it as of hydrochloric acid is required to produce energetic digestion.

Dr. Leube has found that, in cases where there has been excessive acidity of the contents of the stomach, which has contained undigested food after several hours, the addition of slightly alkalisied pepsin did not increase the digestive property of the fluid.

He believes that, in the treatment of gastric diseases, hydrochloric acid is, in most cases, of more

* *Virchow's Archiv*, vol. iv, and *Centralblatt für die Medicinischen Wissenschaften*, 1871.

use than pepsin, from which, in modern times, much has been expected; but that the administration of pepsin together with the acid is indicated in those cases in which the acid alone fails to produce the desired result. According to Panum's latest researches, the most efficient preparation is the essence of pepsin, prepared according to Liebreich's formula by Schering, of Berlin; and next to this comes 'French pepsin,' a mixture of pepsin, peptones, and lactic acid.

An abundant secretion of mucus in the stomach interferes with the normal production of acid, and gives rise to abnormal products of digestion. But the assumption is not well founded, that to the presence of the mucus is to be attributed the fermentation which results in the formation of acetic, butyric, lactic, and carbonic acids, and hydrogen. If the quantity of these abnormal products of fermentation be too great, one can only administer carbonate of soda or some other antacid. This is the more indicated, as the alkali not only neutralises the acids, but also, as soon as it is in excess, promotes normal secretion from the walls of the stomach.

A change in the quantity of the gastric juice may be a cause of dyspepsia, although its constituents are in normal proportion. Persons suffering from this form of dyspepsia endeavour to rouse the torpid mucous membrane of the stomach to action by the use of strong condiments or other stimulants. Direct evidence of such a pathological condition is afforded in the following way. If, in a healthy individual, the tube of the stomach-pump be introduced during fasting, the mechanical irritation produced by it, and that of the cold water injected, are sufficient to produce a slight secretion from the mucous membrane, and the fluid which escapes through the tube has a slightly acid reaction. But when the digestive power is torpid, this mild irritation is no longer capable of exciting the glands to secrete. I know a man, the subject of slight digestive disturbance, from whose stomach I can never obtain anything but a neutral fluid; and in the case of a lady whom I have lately had under treatment for dilatation of the stomach, the fluid obtained by washing out the organ has always had a neutral reaction. Such cases of total defect of secretion of gastric juice are treated by rhubarb, ipecacuanha, &c. I am of opinion, that, in the treatment of this torpor of the mucous membrane of the stomach, we should trust less to the action of these medicines than to the gradual weaning of the stomach from any vehement stimulants. To carry this out, requires much patience on the part of both physician and patient. In cases where quicker aid is required, we may prescribe remedies which have been shown by physiological experiment to be capable of producing an increased secretion of gastric juice. Such remedies we possess in ether, alcohol, cold water, the alkalies, very probably in bitters; and here also benefit is to be expected from the use of the alkaline waters of Vichy, Bilin, &c. As adjuvants, ice and bitters are useful; the action of these, as I have recently shown, is indirect; they probably only produce an increased secretion of saliva, which, being swallowed, acts as a powerful stimulant on the gastric mucous membrane.

Dr. Leube then proceeded to speak of the absorption of peptones. Experiments on artificial digestion have shown that the process is interrupted, unless the peptones be removed by dialysis; and if the absorbent power of the gastric mucous membrane be impaired, the escape of the peptones from the sto-

mach is interrupted, and disturbances of digestion are the result. In this way is explained the observation of Ranke, that, of equal and similar quantities of meat, more was digested when it was used in small portions, than when the whole was introduced into the body at a single meal. Thus also are explained various clinical observations. Starting from the assumption that deficient absorption of peptones may be a cause of dyspepsia, we may readily attribute a portion of the disturbances in chronic gastric catarrh to a diminution in the absorbent power of the mucous membrane. Especially clear, in my opinion, is the action of this defective absorbent power in dilatation of the stomach. When the absorption of peptones by the mucous membrane is interrupted, the products of digestion along with the undigested food accumulate in the stomach, and lead to its gradual distension. It is self-evident that such an accumulation is favoured in cases where there is a mechanical impediment—such as a stricture following the cicatrization of an ulcer—to the passage of the gastric contents through the pylorus. But the whole of the symptoms in dilatation cannot be ascribed to narrowing in the neighbourhood of the pylorus, because the degree of distension of the organ found after death is not unfrequently much greater than can be accounted for by the pyloric constriction; and this state of matters can be easily brought into harmony with the symptoms during life, if the diminished absorbent power of the mucous membrane be also taken into account. The last named functional disturbance explains in a simple way how it is that, in cases of dilatation of the stomach, the organ is again enabled, after the use of the stomach-pump, to propel the food through the narrowed pyloric orifice. We have noticed in cases of this kind that, after several removals of the accumulated and unabsorbed collections of fluid, often in enormous quantities, the stomach again began to absorb. In this way, a portion of the burden thrown on the muscular structure of the stomach is removed, its work becomes easier, and it gradually regains the power of propelling onwards the contents. That the defective absorption of peptones must interfere with nutrition is evident: most practitioners must have met with cases of emaciation originating in dilatation of the stomach.

The actual existence of such arrest of absorption, may be demonstrated in a similar way to that employed in determining the existence of impaired digestion from torpidity.

A patient, sent to me by my honoured colleague Pfeiffer, had suffered during several years from gastric oppression, eructation, vomiting of large masses of the contents of the stomach, and considerable emaciation. When he lay on his side, the fluid in the stomach fell over to the same side with a loud noise, and a squashy fluctuation could be perceived on palpation. The patient himself felt as if the fluid simply fell down when he drank. The distance to which a tube could be passed, eight centimètres beyond the xiphoid process—removed all doubt that the case was one of extensive dilatation of the stomach. In the course of the treatment, I used only a solution of meat containing peptones, and allowed the patient to eat nothing else for twenty-four hours. On removing the contents of the stomach at the end of this time, the amount of peptones was found nearly unchanged, indicating that very little if any had been absorbed.

Unfortunately, we possess no remedies by the use of which we may hope to excite the absorbent power

of the stomach even in a moderate degree; but, by a more accurate diagnosis, we gain this—that we are saved from giving medicines needlessly. In such cases, I find the most rational treatment to consist in regularly washing out the stomach. For this purpose, I have for several years used, instead of Kussmaul's stomach-pump, a simple siphon. By using this latter instrument, we avoid the risk of sucking up the mucous membrane and lacerating it—an accident of which Ziemssen has lately published an example. Washing out the stomach has been found an excellent remedy in the practice of others as well as in my own. I assure you, indeed, that without the stomach-tube I could not treat this disease, which is very common in Thuringia. I have often convinced myself that all medicines, all dietic regulations, all clinical and physiological calculations, were of no use in such cases, but that the employment of the tube at once changed the aspect of the case for the better.

Along with the regular washing out of the stomach, a diet is to be ordered in which the quantity of fluid is extremely limited. I allow my patients to take small pieces of ice or of fruit-ices, and advise them always to take food only in small quantities. In this way we may soonest expect the stomach to recommence the absorption of small quantities of peptone. This treatment may be assisted by the application of hot poultices to the epigastrium, which, when applied to other parts of the body, are found to be the best means of improving the absorbent action in deeply lying organs, as in chronic peritonitis and pleurisy. It is also advisable to suspend the action of the stomach from time to time, and to give rest to the organ long overburdened with labour; and this is best attained by the use of meat and pancreas clysters. That in many cases hydrochloric acid also is useful, has already been pointed out.

Having tested this last-named method of treatment on patients, I am well aware that it does not afford the means of directly and permanently restoring the absorbent power of the stomach. As long as our knowledge of the process of absorption, and especially of its preliminaries, is limited, so long we can certainly scarcely dare to hope to find the panacea for these conditions.

We must now examine the changes which take place in the function of the muscular coat of the stomach. Besides propelling the chyme from the stomach, the muscular contractions very probably bring it into intimate contact with the mucous membrane, so that it becomes impregnated with the gastric juice; further, they favour the formation and absorption of peptones. If the portions of food remain at rest in the stomach, the peptones are accumulated where they are formed, at the periphery of the masses of food, and the further peptonisation of the albuminous substances in the food is prevented.

The movements of the stomach favour the solution of digestible substances, and also promote absorption. As in other parts of the body, so also in the stomach, muscular contraction is a powerful factor in the propulsion of lymph and of venous blood, and consequently in the maintenance of absorption.

Any impediment to the activity of this so important mechanical aid to gastric digestion, must interrupt the process and lead to dyspepsia. In his well-known work on the use of the stomach-pump, Kussmaul has directed due attention to the behaviour of the muscular tissue in dilatation of the stomach,

and has shown the existence of fatty and colloid degeneration of the muscle-cells in severe forms of the disorder. But simple weakness of the muscular structure, such as may be met with in chlorotic and in aged persons, or serous infiltration, such as may occur in Bright's disease, in disease of the lungs or heart, or even in catarrh of the mucous membrane, is sufficient to interfere with the important aid which the process of digestion receives from the muscular contraction. Dr. Leube says that he has used electricity as a remedy, but his observations are as yet too few to allow more than the expression of hopes and hypotheses. I only know, he says, that in many cases the current has a good effect; and that there is no physiological reason why it should not act on the muscular coat of the stomach through the abdominal walls.

It is possible that certain forms of dyspepsia are due to nervous influence. At least, it is known that in cases of hypochondriasis, hysteria, diseases of the sexual organs, neuralgia, &c., dyspepsia occurs, the genesis of which must be for the present attributed to reflex influence. But, as we know little or nothing of the course of the nerves which regulate secretion, the existence of 'nervous dyspepsia' is at most doubtful; and, at the bedside, we should avoid as much as possible referring this or that form of dyspepsia to the nervous system.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

THIN ON THE STRUCTURE OF THE TACTILE CORPUSCLES.—Dr. Thin (*Journal of Anatomy*, December, 1873), says that the examination of fresh skin after treating it by chloride of gold, osmic acid, and carmine, and acetic acid, shows that there are two kinds of tactile corpuscles, single and compound; the greater number belong to the latter category. A vertical section through the meridian of a tactile corpuscle shows either a simple more or less rounded body enclosed in a capsule, or two or more such capsulated bodies arranged in a row parallel to the vertical axis of the papilla, and enclosed in a common oblong capsule, the former representing a single, the latter a compound corpuscle. Compound corpuscles may again be divided into twins, consisting of two, and triplets, consisting of three single corpuscles; each of these individuals may be termed a member of the corpuscle. The space which separates the members of a compound corpuscle varies in breadth, and is only well marked in osmic acid preparations.

Each single corpuscle and each member of a compound corpuscle is penetrated invariably only by one medullated nerve-fibre; before piercing the capsule it describes a curve or a complete spiral, or forms a loop, or simply follows a straight course. If the corpuscle be single, the nerve penetrates at once into its interior after having pierced the capsule. If it be compound, the nerve, having penetrated the capsule, either immediately enters the member opposite its point of entry, or takes an upward course within the common capsule towards the member to which it is destined. In this course it follows no fixed rule, sometimes running parallel to the long axis of the corpuscle, sometimes crossing it once or even twice transversely. When the nerve has entered the substance of the corpuscle, it penetrates

to a certain depth either in a straight line or in a curve, but retains still its medulla.

Thin denies the alleged division of the medullated nerve in the tactile corpuscle.

The capsule of the tactile corpuscle consists of a circular layer of elastic tissue formed by the anastomosing processes of cells.

In teased gold and acetic acid and carmine preparations, it is seen that the well-known transverse elements of the tactile corpuscle are the nuclei of oblong cells, which anastomose with each other by means of processes of elastic tissue fibres. This dense network of cells and elastic fibres represents, in fact, the greater part of the substance of which the tactile corpuscle is composed. The network of elastic tissue in the corpuscle, and the cells connected with it, in no way, communicate with the medullated nerve-fibres.

The division of the papillæ of the skin into vascular and nervous is not borne out by the observations of the author; for in the majority of so-called nerve-papillæ there are, beside the tactile corpuscle, also one or more capillary blood-vessels.

MARTIN ON THE STRUCTURE OF THE OLFACTORY MUCOUS MEMBRANE.—Dr. H. N. Martin (*Journal of Anatomy and Physiology*, December 1873) confirms the well-known assertions of Max Schultze, that the epithelium covering the olfactory mucous membrane consists of two kinds of cells, viz., true epithelial and olfactory or sensory cells, which in anatomical respects are quite different. The correctness of these assertions had been questioned by Exner, who maintained that both these kinds of cells gradually shade off into one another.

In the newt, these two kinds of cells are very distinct. In a teased preparation of the olfactory membrane prepared with Müller's fluid, it can be seen that the epithelium consists of groups, each of which is formed of a central true epithelial cell with a number of olfactory cells grouped around it. In agreement with Max Schultze, Dr. Martin describes the true epithelial cells as being possessed of an oblong nucleus, whereas the olfactory cells have a spherical nucleus. In agreement with Exner, Dr. Martin describes the central process of the true epithelial cells as being generally branched. The central process of the olfactory cells is thinner than their peripheral process; it exhibits varicose enlargements, and does not divide. Dr. Martin has not been able to find cilia on the peripheral process of the true epithelial cells, as described by Exner. In the frog the two kinds of cells are not so readily distinguished as in the newt, the nucleus of both being oval, and the central processes of the true epithelial cells being fewer and less branched, and finally the peripheral processes being not relatively so thick compared with the corresponding processes of the olfactory cells.

In the dog, also, the two forms of cells are quite distinct, although both differ from those of the newt. In the true epithelial cells the nucleus is smaller and rounder than in those in the newt; the central process is comparatively thick and has little angular prominences here and there upon it. It is always single, and never branched until towards its deeper end, where it swells out into a large knot; from this a number of short thick processes arise, whose general direction is parallel to the surface of the mucous membrane, and which join those of neighbouring cells so as to form an irregular network with

small meshes. Each process contains just above its terminal enlargement a number of granules, which stain very deeply with osmic acid.

The olfactory cells are proportionately less numerous than in the newt, and their central processes are finer; their nuclei are oval and rather smaller than those of the true epithelial cells.

E. KLEIN, M.D.

KOCH ON THE CHANGES WHICH CERTAIN MECHANICAL AND CHEMICAL IRRITANTS PRODUCE IN THE PULMONARY PARENCHYMA.—W. Koch (*Langenbeck's Archiv für Klinische Chirurgie*, vol. xv.) reports experiments conducted with all necessary precautions, in which the lungs of animals were subjected for a varying length of time to irritations produced either by the introduction of an acupuncture needle, or by the injection of solutions of iodine varying in strength from 1 in 120 to 1 in 20. The results have always been the same. The animals did not evince any signs of pain or of other general disturbance; only in a very few instances, in which the solution of iodine was very strong, the parenchymatous injection was followed by a short cough. There was no increase in temperature or in the frequency of respiration. On *post mortem* examination, it was found that the irritated pulmonary parenchyma was converted into connective tissue.

The present experiments allow the conclusion that it is possible to convert pulmonary into connective tissue by means of parenchymatous injections of iodine, without producing constitutional disturbance of any kind.

I. B. BERKART, M.D.

KOHLER ON LOCAL ANÆSTHESIA FROM SAPONIN.—The *Berliner Klinische Wochenschrift* for July 6, 1873 (no. 27), contains a review of a monogram by Dr. Köhler, entitled 'Die lokale Anästhesie durch Saponin: experimental-pharmakologische Studien,' which offers several points of interest to both medical and surgical readers. This work is the outcome of very numerous experiments made on frogs, dogs and rabbits, with a view of determining the physiological effects of this substance. Pelikan was the first to discover its local anæsthetic effects, and Köhler has not only confirmed his statements, but brought out new and interesting facts. Saponin, or struthin, variously called githagin, quillajin, senegin, and monesin, is a glucoside, and occurs in many plants of the natural orders of the Silenæ (*e.g.* *Saponaria officinalis*) the Polygalacæ (*e.g.* *Polygala senega*) of the Spireæ (Rosacæ) (*e.g.* *Quillaja saponaria*) and the Sapotacæ (Cortex monesinæ); it is an amorphous white powder, with neutral reaction and sweetish taste; it is soluble in water, forming a foaming fluid like soap-suds. The experiments made on it proved its local effects, as well as those on the muscles and nerves of the extremities by subcutaneous injections, on the exposed hearts of frogs, on the intestines, and on the nervous centres by direct application to these organs; then the general effects from injections into the jugular veins; and lastly, the symptoms produced by its introduction into the stomach. The most important local effects are as follows. Five minutes after the application of a few drops of a concentrated solution, there occur perfect suspension of the reflex irritability of the part selected, and paralyses of both motor and sensory nerve-filaments. Shortly afterwards, the muscles of the part lose their power of responding to chemical, mechanical, or electric

irritants; and this may occur somewhat independently of the nerves. The nerve-trunks, and afterwards the nervous-centres, do not become affected till larger quantities of the solution are applied, and then probably by absorption, as the effects become general. The capillaries, at the spot selected for injection, become greatly contracted, and so do the larger vessels, such as the vena cava and aorta, when the saponin is applied directly to them. When it is applied directly to the heart, the beats of this organ gradually become less frequent, and then cease altogether. This effect does not depend upon irritation of the terminal branches of the vagi, but on paralysis of the accelerator nerves (sympathetic), which thus raises the 'tonus' of the vagus-filaments. Finally, paralysis of the cardiac ganglia themselves (*i.e.* of those imbedded in the muscles of the heart) ensues. In a like manner, direct application of the solution to the abdominal organs first paralyses their muscles and then their nerves. Local application to the nervous centres induces, at last, complete paralysis of these organs. This spreads peripherally from the spinal cord; and, continuing to affect the medulla oblongata and the cerebrum, produces asphyxia (stoppage of respiration), deep coma, and dilatation of the pupils. The series of experiments made by injecting saponin into the vena cava of warm-blooded animals produced these effects: diminution of blood-pressure, succeeding a slight temporary increase of it; reduction of temperature and of the frequency of both respirations and cardiac contractions. The effects on respiration and upon blood-pressure are produced through the nervous centre for these functions. The spinal cord and the peripheral muscles and nerves are not paralysed by these injections into the veins. Lastly, when saponin is introduced into the stomach, blood-pressure is reduced, and pulse, respiration and temperature, all sink, though slowly; paralyses of the extremities (as in the injections into the veins also) does not occur in this case. No alteration in either the quantity or quality of the excreta have been observed. Clinical practice only can decide whether saponin may play a great part in surgery as a local anaesthetic—the experimenters believe that to be probable—meanwhile the physiological effects (on the heart, and respiration, &c.) deserve further study, as it is very possible that larger doses may be safely given to human beings than were tolerated by any of the animals experimented on.

W. BATHURST WOODMAN, M.D.

MEDICINE.

ROSENSTEIN AND SÄNGER ON HYDATIDS OF THE SPLEEN.—The *Berliner Klinische Wochenschrift*, of May 19, 1873 (no. 20), contains a communication from Professors Rosenstein and Säger, of a case of recovery from echinococci of the spleen. As such cases are very rare, we abstract the following particulars. Mrs. K—, from Friesland, aged thirty-seven, had enjoyed good health except from occasional attacks of intermittent fever. Married at twenty-one, she had had six children, and had once aborted. Shortly before the last confinement, two and a-half years ago, she first felt pain in the left side, which gradually increased in severity, and after the confinement never entirely ceased. For about a year she noticed a swelling in the seat of the pain, which gradually increased up to the

day of her reception into the hospital, the pain increasing also.

Her state on January 2 was as follows. She was well built, fairly nourished, but pale and anæmic. The lungs, liver, and heart, appeared healthy. Her abdomen was unsymmetrical, and the left side was specially distended. Splenic dulness began at the ninth rib, and merged into the obscure percussion-note of a tumour which extended under the left border of the ribs, and gave rise to unsymmetrical distension of the belly. To the right and below, the outlines of the tumour could be made out by inspection; on the right it was bounded by a convex line, beginning at the xiphoid cartilage, cutting the linea alba, and reaching its greatest distance from this, equal to about 8 centimètres (a little more than 3 inches). Below, the boundary line ran more irregularly in an arched line which reached 7 centimètres below the navel (a little less than 3 inches). Fluctuation was very distinct. Manipulation was painful, but the skin was not reddened. The tumour was not movable, and was not affected by the respiratory movements. On the right border, the dull percussion-note passed at once into a clear tympanic tone. Her health was only disturbed by the pain. All her functions were fairly performed. The form and situation of the tumour suggested hydronephrosis; but the unusually clear fluctuation and its relations to the bowels, which did not lie in front but to one side of it, and the fact that the lumbar region and the left side of the body were never abnormally distended, at once negated this. Nor were the renal functions ever disturbed. A splenic tumour was diagnosed, although it was unaffected by respiration and no notch could be felt. Puncture with a grooved needle gave exit to a clear watery fluid, which had a specific gravity of 1.007, but gave evidence of albumen both by boiling and by nitric acid. The search for inosite and succinic acid, and for morphological elements, was prevented by an accident. After puncture, the tumour was lost both to sight and feeling. The percussion-note became tympanitic over the tumour, and splenic dulness reached one finger's breadth below the last ribs. But, after a few days, the tumour filled again. The pain became so severe as considerably to accelerate respiration. On January 13 the swelling had attained a length of 17 centimètres (6.6 inches), and a breadth of 16 centimètres (6.25 inches), and on the 18th of that month 150 cubic centimètres of purulent fluid (5 ounces nearly) were removed by puncture with fresh relief to the symptoms, though she had slight febrile disturbance of an intermittent type. The cyst filled again, and 600 cubic centimètres (nearly 1 pint English) of purulent fluid were then withdrawn, the length of the tumour having reached 30 centimètres (nearly 12 inches). As no hooklets could be discovered, nor any other specialities in the purulent fluid, the diagnosis could only assert that there was a cyst connected with the spleen.

As her pain became greatly increased, a radical operation was decided upon. On March 17, an incision 12 centimètres (between 4 and 5 inches) in length was made obliquely from the left border of the ribs towards the navel, and the muscles were divided on a director. There were adhesions between the transversalis fascia, the peritoneum, and the tumour. As the extent of these adhesions was not evident, it was thought advisable to secure the sides of the cyst to the margins of the opening by

ligatures. When this was done, a second incision was made at right angles to the former, and then a smooth-walled cyst could be felt in the interior of the cavity, and, by means of forceps and fingers combined, it was drawn out. The wound was treated with carbolised charpie, and in three weeks was perfectly healed. The cyst which was extracted consisted of an outer laminated wall of its own, the single layers of which could be separated by the nail; perfectly smooth on the outside, and coarsely granular, with a brownish-yellow tint internally, and of jelly-like consistence. In this were found some small bladders, varying from the size of a pea to that of a hazel-nut, which, under the microscope, showed a similar laminated structure to the outer wall of the mother-cyst. No scolices nor any of their elements could be detected. It was, however, evident that the cyst was a sterile echinococcus, the so-called acephalocyst of Laennec.

The authors point out that the case is peculiar in several respects. 1. There was an isolated echinococcus of the spleen. Davaine gives an analysis of 166 cases in the liver, but gives no details of one in the spleen. Förster gives 8 cases, viz., those of Günsburg, Andral, Cruveilhier (2 cases), Albers, Boehdahlen, Leutner, and Duplay. In all, except Duplay's, the splenic hydatid was first found at the necropsy, and (unless perhaps in one of Cruveilhier's cases) there were also hydatids of the liver. In Legroux's case, which ended fatally under treatment by Récamier's method, the tumour hardly belonged to the spleen. In the case narrated there were no signs of liver-disease. 2. The extreme painfulness of the tumour differed from the common history of liver-hydatids. The patient could not bear to move, and drew only shallow breaths. This does not agree with Canstatt's remark:—'The same remarks which apply to similar formations in the liver may be applied to acephalocysts and echinococcus-cysts in the spleen,' a remark which is copied into many text-books. Even Davaine says: 'Their pathological effects, if we except the phenomena resulting from compression or ulceration of the biliary passages, are analogous to those produced by cysts of the liver.' 3. The presence of albumen in notable quantity in the contents of the cysts at the first tapping is remarkable. For the absence of this, ever since Redi first pointed out that it was absent in hydatid fluid, and Récamier insisted on the importance of this negative symptom, has been made a diagnostic mark, as regards hydatids of the liver. In this case, the albumen and the want of structural elements (afterwards explained by the sterility of the echinococcus) long made the diagnosis doubtful. In future cases of splenic hydatids, these points would be worth investigating.

[The reporter has only met with one case of hydatids in the spleen, except where other organs were implicated, in a large number of *post mortem* examinations witnessed by him. He has, however, seen several cases of hydatid tumours where the great pain felt by the patients gave rise to the suspicion of malignant disease. In one or two of these, the pain, and perhaps pressure-effects, had also induced great emaciation. As regards the fluid from hydatid cysts, the reporter, from the examination of numerous specimens, is able to affirm that it is not at all uncommon to find traces of albumen in the fluid, whilst it is very rare to find quantities such as are found in serous effusions. The specific gravity varies from 1.005 to 1.010 or 1.012, hardly ever more, if there has been no suppuration; and there is always

a large quantity (relatively to the specific gravity and saline constituents) of chlorides, chiefly of sodium and potassium.—*Rep.*]

SEGUIN ON PHYSIOLOGICAL THERMOMETRY.—Under the title of *Thermomètres Physiologiques et Thermométrie Mathématique, leur application à la Médecine, à la Chirurgie, à l'Éducation* (Paris: J. B. Baillière; London: L. P. Casella), Dr. Edouard Seguin reprints in a condensed form, from his abridgment of Wunderlich's Thermometry, his former proposal to graduate medical (or, as he calls them, physiological) thermometers on a new and arbitrary scale, as under. He makes 37° Centigrade (or 98.6°) his zero, normal or line of health.

| | New Degrees. | Fahr. equivalents. | Remarks. |
|-----------------------|----------------|----------------------|--------------------------------------|
| Degrees above normal. | 7° | 111.2° | No recovery certified. |
| | 6° | 109.4° | Almost always mortal. |
| | 5° | 107.6° | Often fatal. |
| | 4° | 105.8° | Intense fever. |
| | 3° | 104° | Considerable fever. |
| | 2.5° | 103.1° | Moderate fever. |
| | 1.5° | 101.3° | Slight fever. |
| Zero | 0 | 98.6° | Normal line of health. |
| Degrees below normal. | 1.5° | 97.7° | Sub-normal. |
| | 1° | 96.8° | Depression. |
| | 2° | 95° | Collapse imminent. |
| | 2° to 3° | 95° to 93.2° | Algide collapse. |
| | 4° to 5° | 91.4° to 89.6° | No recovery known except in cholera. |

This graduation is very ingenious, but we must deprecate the introduction into the sick room of any instrument with such alarming statements on its stem; and we cannot help demurring to some of the statements themselves, for in malarious fevers and sunstroke there have been recoveries from very high temperatures, whilst exceedingly low ones have been met with and recovered from in cases of intoxication, as well as similar temperatures in cholera. This, however, does not affect the principle of the graduation; and it is to this we chiefly object, because, now that the centigrade scale is so largely employed by chemists and physicists, and even by engineers and manufacturers, it must surely be a retrograde step to introduce into medicine a new scale which would still further disserve it from the collateral sciences. Dr. Seguin reproduces from his other work his pet 'surface thermometers,' which are little to be relied upon, especially if held with a [?] warm hand upon any part. The 'clinical tables' drawn up by Dr. Seguin are as excellent as the surface thermometers and new scale are faulty, and there is no doubt that intelligent nurses, whether private persons or professionals, furnished with such tables, might greatly aid the doctor. Our own experience, however, is that it takes a great deal of training before the majority of even medical students can be trusted to fill in such tables. For the use of students who have been so trained, and for practitioners themselves, such records are invaluable; though for the purpose of comparison of cases the graphic method, which is so distasteful to Dr. Seguin, is far easier to apprehend, and to make others see with the same eyes as we ourselves do. These criticisms are not made in any unfriendly spirit towards Dr. Seguin, who has perhaps done more than any other of Wunderlich's pupils to advance medical thermometry, and is well known both in England and America for his works on Idiocy and the modes of teaching deaf-mutes. His little pamphlet, whatever its merits in other respects, would be well worth the price (only half a franc) if only for the

table of equivalents of thermometric scales which forms its appendix.

W. BATHURST WOODMAN, M.D.

DISEASES OF CHILDREN.

TARUFFI ON CONGENITAL CEREBRAL HERNIA. Professor Taruffi, in an article on this subject in the *Revista Clinica di Bologna*, sums up in the following conclusions (*Gazzetta Medica Italiana-Lombardia*, October 25.)

1. Congenital cranial hernia occurs in children in whom the bones of the vault of the skull are relatively well-developed, as well as in those in which they have remained in great part membranous; as may be the case in infants in whom the skull, though complete, has remained small and contracted.
2. In all these cases, the hernia takes place both through the fontanelles and sutures, and also through the bones of the vault of the skull or the base, but more frequently in the middle line of the head, especially in the occipital region, than in any other part.
3. The frequency of occipital hernia depends either on the position of the head in the uterus, or on the direction in which the intracranial distending cause operates.
4. In completely formed skulls, herniæ are formed either of the meninges alone, or also of the cerebrum, which in many cases is dropsical. In the membranous skull the hernia consists of cerebrum only, which is rarely dropsical.
5. Meningeal herniæ consist of serous accumulations in the dura mater. It is probable, however, that some have their origin in circumscribed subarachnoid dropsy.
6. The etiology of purely cerebral herniæ is very obscure. In some cases, however, either an anomaly in the form of the brain (general or partial hypertrophy, or malformation) or synostosis of the parts of the sphenoid bone, has been recognised. With encephalocele is sometimes associated meningocele, which may be considered as a result of the incarceration of the hernial sac.
7. Herniæ, with dropsy of the ventricles, are due to the latter as their cause; it may be either general or partial. General dropsy of the ventricles gives rise to hydro-encephalocele and not to macrocephalus, when the bones are not divaricated, and are not thinned in proportion to the increase of the size of the brain.

A. HENRY, M.D.

EHRENDORFER ON THE USE OF NESTLÉ'S CHILDREN'S FOOD.—Dr. Felix Ehrendorfer (*Fahr-buch für Kinderheilkunde*, vol. vii. p. 78), says that many attempts have been made to find a substitute for the mother's milk; these have been the more necessary on account of the adulteration of cow's milk in large towns. To these endeavours we owe Liebig's malt food, Löfflund's food, also the condensed milk of Cham in Switzerland and of Kempen in Bavaria, and lastly, Nestlé's children's food. The composition of Nestlé's food is a secret; Ehrendorfer believes it to be made up of wheaten flour, condensed milk, yolk of egg, and sugar. The flour is converted into dextrin by overheated steam at a pressure of a hundred atmospheres. Chemically, it consists of 40 per cent. of sugar and milk sugar, 5 per cent. of fat, 15 per cent. of protein matter, 30 per cent. of dextrin, and starch. One table-spoonful (one ounce) of the food is rubbed up with six table-spoonfuls (3 ounces) of water, and the mixture is boiled for a few minutes. It is given twice or thrice a day. One spoonful of food treated

with eight or ten spoonfuls of water will serve for a drink between meals. The food does not suit children under six weeks of age. In older children it can be given alone, and to supplement imperfect suckling. It has been used in cases of simple insufficient feeding, dyspepsia, enteric catarrh, and enteritis. The results were satisfactory; at least, as good as those obtained from other modes of artificial feeding, although not clearly better. On the whole, the food seems to be more adapted, in all cases, to children over six months of age than to younger children.

REHN ON ULCERS OF THE STOMACH IN CHILDREN.—Dr. H. Rehn (*Fahrbuch für Kinderheilkunde*, vol. vii. p. 19) discusses fully the whole subject of gastric ulcers in children. He speaks of seven kinds of ulcer—catarrhal, hæmorrhagic erosion, tubercular, follicular, simple perforating, gangrenous, diphtheritic. This order indicates the relative frequency of occurrence, gangrenous and diphtheritic ulcers being uncommon. The only kind of ulcer which is in any way peculiar to childhood is the follicular ulcer. Billard was the first to describe a disease of new-born children by the name of follicular gastritis. Dr. Rehn refers to the opinion of Bohn (*Die Mundkrankheiten der Kinder*, Leipzig, 1866), that, if by the word follicle be meant a lymphatic follicle, these ulcers are not follicular; lymphatic follicles are not commonly present in the stomach of newborn children. The minute mucous follicles are at fault; their mouths are plugged by a plug of epithelium; minute mucous cysts result, and also, if the plugs do not escape, inflammation and ulceration. Rehn concludes that the exact nature of this follicular gastritis is not yet ascertained.

VON HÜTTENBRENNER ON THE TREATMENT OF TETANUS AND TRISMUS NEONATORUM WITH CHLORAL-HYDRATE.—Dr. A. von Hüttenbrenner (*Fahrbuch für Kinderheilkunde*, vol. vii. p. 30), from observations made by himself and others, has come to the following conclusions. Tetanus of the newly born is not an absolutely mortal disease. It is accompanied by fever or not. Those cases which are very febrile and acute are probably dependent upon a general blood-poisoning, and the fever-free cases are to be looked upon as reflex spasm consequent upon peripheral excitation. The prognosis is more favourable in the non-febrile than in the febrile cases, although even in the latter recovery may occur. Chloral is by no means a specific for tetanus, yet is to be preferred to all other medicaments, and for these reasons. It is a simple hypnotic; it is not accompanied by the disagreeable consequences of morphia, especially the cerebral hyperæmia; it is easily given to children, with a very small risk of cumulative excessive action. The dose is one or two grains dissolved in the mother's breast-milk, obtained for the purpose, and carefully poured through the child's nose. The dose must be repeated with each paroxysm, until the child passes into enduring sleep. The administration by the nose is usually followed by a severe paroxysm. SAMUEL GEE, M.D.

THE Order of the Red Eagle of the second class has been conferred on Professor Bardeleben and Du Bois-Reymond, of Berlin; and of the third class on Professor Virchow, of Berlin, and Professors Schultze and Veit, of Bonn.

MATERIA MEDICA AND THERAPEUTICS.

SIEGEN ON THE ACTION OF EUCALYPTUS GLOBULUS; WITH SOME EXPERIMENTS ON FEVER.—This subject has lately been investigated under the direction of Professor Binz of Bonn, by Theodor Siegen (*Ueber die Pharmacologischen Eigenschaften von Eucalyptus Globulus*: Inaugural Dissertation). The oil of eucalyptus having been proposed as a substitute for quinine, experiments were made for the purpose of ascertaining whether it possessed the same antiseptic action which quinine has been proved by Binz to possess. These showed that eucalyptol is quite as powerful in this respect as quinine, and like it prevents decomposition in albuminous solutions or blood, and retards the growth of fungi in solutions of tartaric acid or tannin, although they grow readily on moist eucalyptus leaves. It hinders alcoholic fermentation much more than quinine does. Siegen quotes an interesting observation of Gimbert, who found that, after the injection of eucalyptol into a rabbit, the blood which was afterwards drawn did not decompose, and the body became mummified but did not decay. Eucalyptol depresses the temperature of the healthy body even more than quinine: 1·35 grammes (21 grains) of it reduced the temperature of a rabbit 2° Cent. (3·6° Fahr.) in one experiment, and 120 drops (4·2 grammes) lowered that of a healthy man 5° Cent. (9° Fahr.), and that too in the evening when it would normally have risen. Four doses of twenty drops taken at intervals of an hour did not impair the appetite, but produced a sort of drunkenness, which in an hour and a half passed into mental depression and exhaustion lasting for several hours.

The sweat had a perceptible odour of trimethylamine. Very little eucalyptol appears unchanged in the urine, but a considerable quantity of resin is to be found in it. This resin diminishes reflex excitability of the spinal cord in the same way as eucalyptol, but more slowly and less permanently.

Eucalyptol diminishes the temperature in fever as well as in health. Some very interesting experiments showed that several organic ferments produced a rise of temperature when injected into an animal. Among these were ferment obtained from fresh pus by Von Wittich's method, diastase, and ferment from the liver. The symptoms produced by the ferment obtained from pus differ from those caused by the injection of pus itself, the rise of temperature being considerable, but the general condition good and the confusion and prostration produced by pus being absent. The rise of temperature which occurs after injection of these ferments is due to their action as ferments, and not to their mere presence in the blood as foreign bodies. This is shown by the rise being absent when the solutions are boiled before injection. Both the ferment of the liver and diastase induce such chemical changes in defibrinated blood as to cause a rise of temperature in it after the mixture has stood for one or two days. Eucalyptol, like quinine, hinders oxidation in protoplasm. From clinical experience, Siegen concludes that large doses of eucalyptol are very beneficial in febrile diseases of the respiratory organs, especially in whooping cough. Large doses (15 drops every two hours in a child eight years old) produced no bad effects. In several cases the eucalyptol acted as an anthelmintic. It ought to be given as an alcoholic solution.

BLAKE ON THE ACTION OF THE SALTS OF SODA AND ALLIED BASES INTRODUCED DIRECTLY INTO THE BLOOD.—Dr. Blake (*Journal of Anatomy and Physiology*, June, 1873) has investigated the action of salts of soda, lithia, caesium, rubidium, thallium, and silver. Those used were the nitrates of soda and silver, the sulphates of lithia and thallium, and the chlorides of caesium and rubidium. When injected into the jugular vein, they arrested the passage of blood through the lungs and greatly diminished the pressure of blood in the arteries in the course of a few seconds. On *post mortem* examination, the lungs of animals poisoned by soda or lithia were found cedematous. In those poisoned by the other metals, the right side of the heart was much distended, and the left nearly empty. All these metals kill by their action on the lungs, either by arresting the circulation through them, or by causing such changes in the pulmonary tissue as rapidly prevent the aeration of the blood. They do not diminish the irritability of the heart, but, on the contrary, prolong its vitality. None of them, with the exception of caesium, have any direct effect on the functions of the nervous system. Although they have such a powerful action in causing contraction of the pulmonary capillaries, they all, with the exception of silver, pass with great facility through the systemic capillaries, unless introduced into the arteries in large quantities. Very much larger quantities can be introduced into the arteries than into the veins without causing death; and it is only when injected into the arteries in quantities large enough for them to reach the lungs in a sufficiently concentrated state to act upon these organs, that they kill. These properties belong to all the more strictly isomorphous members of the group. The only exceptions are caesium and silver, the latter being evidently an outlying member of the group.

The former exerts a decided action on the nervous system when introduced into the arteries, and a small quantity of a silver salt in the arterial blood causes obstruction to its passage through the systemic capillaries. The arrest of the pulmonary circulation may be due either to contraction of the pulmonary capillaries or to changes in the shape of the corpuscles. In the blood of an animal poisoned by caesium, the corpuscles in the venous blood were thickened and crenated. In the left side of the heart not a single crenated corpuscle was found. The corpuscles never formed rouleaux. The molecular movements were very active many hours after death. The nitrate is much more poisonous than any of the other soda salts.

T. LAUDER BRUNTON, M.D.

GRISAR ON THE ACTION OF ETHEREAL OILS.—A very interesting research on this subject has lately been made in the laboratory of Professor Binz at Bonn. Under his direction, Grisar (*Experimentelle Beiträge zur Pharmacodynamik der Ätherischen Oele*: Inaugural Dissertation), has experimented with oil of valerian, oil of chamomile, oil of eucalyptus globulus, camphor, and oil of cummin. All these substances, when administered to frogs in less than the fatal doses, greatly diminish reflex excitability. This action may continue for a period of several days, varying according to the quantity and kind of oil used. Camphor has the strongest and most persistent action, and after it come in order the oils of valerian, chamomile, eucalyptus, and cummin. A stage of excitement almost always precedes the depression caused by camphor or the oils of valerian, chamomile, and cummin. This is due to the fact

that a small quantity only is absorbed at first, and this has a stimulating action, but, as the absorption goes on, the depressing effect succeeds. Small doses of ethereal oils have a stimulating action only. This disappears at the end of a few hours. Ethereal oils depress reflex excitability by acting directly on the cord, and not by stimulating the inhibitory centres in the brain. This is evidenced by their lessening reflex excitability after the cord has been divided and thus separated from the brain.

Another series of experiments showed that ethereal oils do not depress reflex excitability in animals under normal conditions only, but do so also when the excitability has been pathologically excited to the utmost by the previous administration of strychnia, brucia, or carbonate of ammonia. They diminish excitability both by acting on the reflex apparatus in the cord (as was shown by the experiments with strychnia), and by influencing those centres in the brain which excite convulsions. This appears from the experiments with carbonate of ammonia, which has been shown by Rosenstein to act upon the brain and produce symptoms exactly resembling those of an epileptic fit. Experiments on rabbits showed that the action of oil of valerian and oil of eucalyptus on warm-blooded animals is similar to that which they exert upon frogs. Oil of chamomile and oil of cummin were not tested, but probably act in the same way. Camphor, on the contrary, produces convulsions in warm-blooded animals. A good example of the connection between physiological action and chemical constitution is afforded by camphor and oil of cummin or cymol. The formula of the former is $C_{10}H_{16}O$, that of the latter is $C_{10}H_{14}$, differing from the other only by the elements of water H_2O . Equal doses of the two preparations were given to two rabbits of the same size. That which received the camphor urinated frequently and died in convulsions, while that treated with cymol presented no abnormal symptoms. In all clinical and other experiments with essential oils, it must be borne in mind that they are very slowly absorbed.

FICK ON THE ACTION OF SPARTEIN.—J. Fick (*Archiv für experimentellen Pathologie und Pharmacologie*, vol. i. p. 397), finds that spartein has an action somewhat analogous to that of conia. Spartein was discovered by Stenhouse, and was found to have the formula $C_{16}NH_{13}$; it differs from conia ($C_{16}NH_{15}$) only by H_2 . 1. Spartein impairs the activity of the brain both in frogs and in mammals, and may therefore to a certain extent be regarded as a narcotic. This action on the brain is by no means intense, and entire loss of consciousness is never observed even when poisoning is most complete. 2. It has a powerful action on the spinal cord, and greatly lessens reflex action. 3. It paralyzes motor nerves, which completely lose their electric excitability after a large dose of the poison. 4. The vagus is completely paralysed by comparatively small doses of the drug, so that irritation of its trunk by electricity no longer produces any inhibitory effect on the heart. Larger doses paralyse the inhibitory centres in the heart itself, so that neither irritation of the venous sinus nor the application of muscarin can produce still-stand in diastole. 5. Spartein appears to produce death in mammals by paralyzing the respiratory centre, and life can be prolonged for a considerable time by artificial respiration.

T. LAUDER BRUNTON, M.D.

DOBELL ON PANCREATIC EMULSION AND PANCREATINE.—Under the title of 'Further observations on the use of these substances in consumption, marasmus, tabes mesenterica, and other wasting diseases of children and adults,' Dr. Dobell reprints a paper which appeared in the *Practitioner* for October 1872, with some additions. We quote from it the following references to the formulæ for their manufacture: 1. 'On the action of Pancreatic Juice upon Fat and Starch,' *Proceedings of the Royal Society*, 1868, no. 97; 2. *Pharmacopœia of the Royal Hospital for Diseases of the Chest* (Churchill's, 1869); 3. *Squire's Pharmacopœias of the London Hospitals*, 2nd edition; 4. *Squire's Companion to the British Pharmacopœia*, 7th edition; 5. The Appendix to Dr. Dobell's work on *Diet and Regimen in Sickness and Health*. 5th edition (Lewis). Some of the cases which, occurred in hospital and private practice are of extreme interest. The reporter knows of other patients, suffering from phthisis pulmonalis, forms of dyspepsia with mal-assimilation of fat, and diabetes, who have derived very great benefit from these remedies, especially pancreatic emulsion. Some of these were treated in the London Hospital by Dr. Langdon Down and other physicians; and some were private patients.

W. BATHURST WOODMAN, M.D.

ATHILL ON SUBCUTANEOUS INJECTION FOR VOMITING OF PREGNANCY.—Dr. Athill (*Medical Press and Circular*), says that the hypodermic injection of morphia occasionally controls the vomiting met with in pregnancy, or that which sometimes follow severe cases of *post partum hæmorrhage*. The formula which he now adopts for the solution to be injected subcutaneously is the following:—

| | |
|----------------------------|---------|
| Acetatis morphiæ | 8 gr. |
| Liquoris atropiæ | 48 min. |
| Glycerini | 5 min. |
| Aquæ, ad | 4 drs. |

Fifteen drops of this solution contains half a grain of the acetate of morphia, and about the fortieth of a grain of atropia.

BERGERET ON GOITRE.—M. Bergeret d'Arbery (*Quelques Cas de Goitre Vertigineux, &c.*, Besançon, 1873) recommends with confidence the employment of iodised kitchen-salt as a remedy in goitre.

BUFALINI ON CAMPHORATED PHENOL.—In a note on the subject (*Campania Medica, and Gazzetta Medica Italiana-Lombardia*, November 8), after noticing the chemical and therapeutic properties of carbolic acid, Bufalini goes on to speak of its behaviour when combined with camphor.

In making experiments with carbolic acid for the purpose of preserving animal substances from putrefaction, Bufalini met with a peculiar phenomenon when it was in contact with camphor. When about equal parts of carbolic acid and camphor are dissolved in alcohol, in about twelve or thirteen hours there arises to the surface of the solution a yellowish stratum of oily appearance; it does not mix with the liquid or with water, nor is the camphor contained in the alcohol precipitated by water. All this indicates that a chemical combination has taken place, forming a substance which Bufalini calls camphorated phenol.

In preparing this compound, Bufalini prefers the two following methods. In the first, one part of carbolic acid and two of camphor broken into small pieces are mixed in a vessel and allowed to stand for

some hours, when a reddish yellow oily liquid will be formed; this is camphorated phenol, which is purified by washing with cold water. The second method consists in dissolving three parts of carbolic acid in ten of alcohol, and five of camphor in twelve of alcohol, mixing the solution in a wide-mouthed vessel, and allowing the mixture to stand for a day or two: the camphorated phenol rises to the top, and may be removed by simple decantation.

Prepared in either of these ways, camphorated phenol is a liquid of oily appearance, reddish yellow or wine-red in colour, having a smell of camphor, insoluble in water, but soluble in alcohol and ether.

Regarding its therapeutic uses, the author gives the following as his conclusions.

1. Camphorated phenol produces the same effects as carbolic acid, but is less dangerous. It may be used both externally and internally—*e.g.* in enteric fever and other infectious disorders.

2. It has the power of modifying unhealthy wounds, and of destroying the parasites which are present in certain diseases, as septicæmia, typhoid forms of fever, &c.

3. The medical use of camphorated phenol is to be preferred to that of carbolic acid, as the former does not present the disadvantages of the latter.

4. Camphorated phenol, when applied to wounds, does not irritate them, or act as a caustic, or disorganising substance on them; and may be used in large doses, without producing symptoms of poisoning.

FORMULARIES.

VARICK ON CAOUTCHOU ELECTUARY AS A REMEDIAL AGENT.—Dr. T. R. Varick (*New York Medical Record*, Nov. 15) recommends caoutchouc as a remedial agent, in preference to cod-liver oil, in certain cases of pulmonary tuberculosis, chronic bronchitis, the winter coughs of old people, and in chronic rheumatism. Prepared in the following manner, the dose is a teaspoonful three times a day, about two hours after meals.

Solution of Caoutchouc.

B. Caoutchouc (in thin slices) . . . 3j;
Oil of turpentine . . . 3ij. M.

Macerate until solution is effected, and strain through coarse muslin.

Electuary of Caoutchouc.

B. Solution of caoutchouc, . . . 3ij
White sugar . . . 3iiss
Honey (strained) . . . 3ijss.

This mixture should be of opaque yellow colour, and thick enough to run very slowly off a spoon. It contains about two grains of pure caoutchouc to each teaspoonful. [What next?]

IODISED SYRUP OF COFFEE.—The syrup of coffee, according to Dr. Calso Aîné (*L'Union Médicale*, Dec. 11) is an excellent means of disguising the flavour of the iodide of potassium, and of rendering this valuable medicine palatable to patients. The following formula is given.

Syrup of coffee . . . 500 grammes.

Iodide of potassium . . . 16 grammes.

Mix.—Take two to three tea spoonfuls daily.

OBSTETRICS AND GYNÆCOLOGY.

VALENTINOTTI ON A CASE OF CÆSAREAN SECTION: APPLICATION OF ELASTIC SUTURES TO THE UTERUS.—Dr. F. Valentinotti, of Trissino in Vicenza (*Gazzetta delle Cliniche*, November 18) had under his care a woman, aged thirty, rickety, and much deformed in consequence, on whom it was found necessary to perform Cæsarean section. The operation was performed on October 2nd, labour-pains having set in; and a living female child, of full time, and strong, was removed. There was no vomiting or hæmorrhage of any consequence. An elastic ligature was applied to one of the uterine arteries, which yielded a rather large jet of blood. Dr. Grandesso Silvestri, who was present in consultation, applied to the uterus four sutures of elastic thread covered with silk, passing the needle through the entire thickness of the organ; in applying each suture, the finger of an assistant was placed between it and the uterus, so as to prevent too great constriction of the tissues. The ends were cut off. The wound in the abdominal wall was united by four ordinary sutures; and strips of adhesive plaster, cotton-wool, and a bandage were applied. On the twenty-seventh day after the operation, the wound in the abdominal wall was quite healed, and the patient was convalescent.

Dr. Valentinotti believes that the elastic suture, by adapting itself to the contractions of the uterus, keeps the edges of the wound constantly in contact, thus favouring union, and also preventing the passage of blood and exudation into the peritoneal cavity.

ROTA ON A CASE OF CÆSAREAN SECTION AFTER DEATH: REMOVAL OF A LIVING CHILD.—Dr. Rota, of Chiari, describes in the *Gazzetta Medica Italiana-Lombardia* for October 16, 1873, the case of a woman aged forty, who, at the beginning of the ninth month of her fourth pregnancy, had œdema of the eyelids, difficult breathing, dropsy of the pudenda and lower extremities, and scanty urine. The symptoms having become urgent, an attempt was made to induce premature labour by the introduction of sponge-tents, but without success. Two days later, having risen to the standing position on account of the severity of the dyspnœa, she fell dead.

The Cæsarean operation was performed by Dr. Rota, assisted by Dr. Pasolari, a few minutes after death: the child, a male, did not at once breathe, but was revived by means of a warm bath, sprinkling with cold water, and artificial respiration after Silvester's method.

A. HENRY, M.D.

DUNCAN ON EFFECTS OF PRESSURE ON THE FETAL HEAD.—Dr. J. Matthews Duncan (*British Medical Journal*, Oct. 18) reports a case in which a persistent digital impression was produced on the parietal bone of a fœtus during birth by the finger of the accoucheur, who was endeavouring to effect artificial rotation. The result was slight, short, but frequently repeated epileptiform seizures, which lasted some time after the digital impression had disappeared, and which were finally replaced by choreic movements.

SAVAGE ON FLEXION IN THE NULLIPAROUS UTERUS.—Dr. T. Savage, of Birmingham, gives a paper (*Obstetrical Journal*, November, 1873)

on flexion in the nulliparous uterus, in which he states that he has treated forty-four women with intrauterine stem-pessaries, without meeting with any ill-effects, so far as he knew, nearly all the cases having been attended, at the least, several times; at all events long enough to be watched and to discover if anything did arise. The chief difficulty, however, which he had was, not the course to pursue, but by what means the stem was to be kept within the uterus; and although he found other kinds suitable, yet, on the whole, he thought the shelf-pessary adapted to the size of the vagina the best mode.

MATTHEWS DUNCAN ON RECURRING UTERINE POLYPUS.—In the *Obstetrical Journal* for November, 1873, Dr. Matthews Duncan narrates a case of recurring intrauterine polypus, which, after the first operation for removal, presented hyperplasia of the glandular structure of the lining of the uterus, without any special indication of malignant affection. It was very soft, and readily crushed by the finger; it sprang from the fundus.

J. BRAXTON HICKS, M.D.

GAJASY ON FATTY DEGENERATION OF THE UTERUS.—Dr. Ludwig Gajasy (*Allgemeine Wiener Mediz. Zeitung*, Dec. 30, 1873) relates an interesting case of this nature occurring in a young woman aged nineteen.

Five or six weeks previously to her admission to the hospital, she stumbled and fell on the abdomen. A swelling gradually formed, which at length prevented her from moving. It was tapped, but only a little sanguineous fluid exuded. The patient gradually became weaker, and died from exhaustion.

On a *post mortem* examination, an extraordinarily hypertrophied uterus, in a state of fatty degeneration, was found to be the cause of the extensive swelling and hardness of the abdomen. The walls were three finger-breadths thick, and thickly sown with fat-globules. The uterine mucous membrane was partly in a state of inflammation, partly loosened, and in places disintegrated.

HABIT ON A CASE OF PLACENTA PREVIA: SIMULTANEOUS EXISTENCE OF A FIBROID TUMOUR IN THE UTERUS.—Dr. Habit (*Allgemeine Wiener Mediz. Zeitung*, Nov. 18, 1873) relates a case where the patient, towards the end of the eighth month of her pregnancy, had recurrent hæmorrhages; and on examination a fibroid was detected in the posterior wall of the uterus.

Turning was accomplished. The child was still-born. The mother recovered from the shock of parturition, but died ten and a half hours subsequently. No *post mortem* examination was allowed.

RECENT PAPERS.

A Case of Extraordinary Presentation of a Malformed Fœtus; with Remarks on some of the Difficulties attending the Births of Monstrous or Diseased Children. By Dr. E. Perro. (*Gazzetta Med. Italiana-Lombardia*, nos. 50 and 52, 1873.)

Extra-Uterine Pregnancy; Rupture into the Rectum. By Dr. Lang. (*Betz's Memorabilien*, vol. xviii. no. 10, 1873.)

DR. AUGUST HERMANN, senior surgeon to the hospital in Prague, and professor extraordinary of surgery in the University, died of hydrophobia on January 7. He had been bitten slightly in the hand by a greyhound about six weeks previously.

REVIEWS.

Les Climats de Montagnes considérés au point de vue Médical. Parle Docteur H. C. LOMBARD. Troisième édition entièrement refondue. 12mo, pp. 232. Genève: Cherbuliez & Co., 1873.

In this new edition of a book, the first appearance of which dates from 1858, Dr. Lombard offers the results of almost a life-long study of the influence of Alpine climates on the human constitution. He gives a general view of the physiological and pathological action of mountain climate in all parts of the world; but the chief value of the work consists in the account of the distribution of disease in Switzerland according to altitude, and in the judicious and impartial survey which it affords of the innumerable Alpine stations in that country, and of their comparative value. On such subjects, Dr. Lombard can speak with the authority due to long experience. From an examination of their meteorological phenomena, he draws these conclusions; that the mountains present an atmosphere colder, lighter, and less variable, than that of the plains; that, while high summits are remarkably dry, there is an intermediate zone, which is moister than the summits, or than the plains, subject also in a greater degree to storms and to electrical disturbances.

The chief physiological effect of residence in mountains he considers to be a sort of carbonic plethora, the result of imperfect oxygenation of the blood. From this doubtful conclusion, we pass on to matters of fact as to the distribution of disease. He divides mountain climates into Alpine and Alpentine; the former being above 6,000 feet elevation, the latter below it. As a rule, Alpine stations are only to be found out of Europe. Passing by the *mal de montagne*, characterised by disturbance of the nervous system and digestion, by a feeling of lassitude and of dyspnœa, which may sometimes last for even months in those recently arrived, Lombard tells us, that the four most characteristic diseases of the inhabitants are (1) anæmia, and the nervous conditions attaching to it; (2) tendency to hæmorrhages and epistaxis; gastric, intestinal, uterine, and pulmonary hæmorrhages are frequent; cerebral hæmorrhage and hemiplegia are not unfrequent; (3) inflammations, as meningitis, pleurisy, and pneumonia; (4) asthma and emphysema are extremely common. While such are the four chief diseases, the following also are frequent: ophthalmia, and erysipelas and irritability of the skin, at great heights; also diarrhœa, dysentery, and hepatitis are not unknown. Rheumatism is general. Typhus and typhoid fever are common in Mexico.

The diseases that are rare, are pulmonary phthisis, and hæmoptysis. Intermittent fever is rarely known. Although, as already said, they have been found high up, diarrhœa, dysentery, and hepatitis have only shown themselves exceptionally in certain places. On the whole, they are not nearly so usual above as lower down. Small-pox and cholera have often been epidemic at a height of 6,000 feet. Yellow fever has not risen above 2,800 feet (?) Scrofula is rather rare in high regions.

We now come to Alpestrine regions, or those which are less than 6,000 feet in elevation.

Pneumonias, pleuropneumonias, pleurisies, pleuritis pestilens, acute bronchitis, are common. Influenza is little known; rheumatism is very frequent, often producing permanent lameness of the hip-joint in old

men; hæmorrhages in general, though not so frequent as in Alpine elevations, are more common than in the plains below; hæmoptysis becomes more and more frequent as one descends to the middle zone, while it is the reverse with epistaxis, hæmatemesis, and metrorrhagia.

Gastralgia and diarrhœa appear to be not unfrequent. There are occasional bad epidemics of dysentery. Icterus and bilious affections are not common; uterine disorders are very much so; intermittent fever is very rare. Unfortunately, eruptive fevers and typhoid are just as virulent as in the plains, though some districts may seem to escape. Asthma, chronic pulmonary catarrhs, and disease of the heart are quite common. Dr. Lombard comes next to consider the frequency of phthisis. After a great deal of investigation he has convinced himself that a certain zone, varying in different districts, but which may be said to lie between 1,200 feet as a minimum, and 3,600 feet as a maximum; in fact, the variable zone already described, though he does not say so, has more phthisis than the region above, or than the region below. This he thinks is absolutely made out for Switzerland, but he is not satisfied as regards the limit for other parts of Europe; and he thinks that in the tropics the line of immunity from phthisis does not descend below 6,000 to 7,500 feet. As to scrofula, it appears to have a zone of prevalence nearly identical with that of phthisis. Much the same applies, though less definitely, to goitre and cretinism, which are common in all mountainous countries, but do not reach to any of the greater heights.

An important chapter is devoted to the diseases, which can be advantageously treated in the Alpine region; for Dr. Lombard remarks that scarcely any of the stations in Europe, where patients reside, exceed 6,000 feet in elevation; the great majority of them are only at a height of about 3,000 feet.

Chlorosis and anæmia profit much, so also does what the French call paludal cachexy. Cases of hyperæsthesia and hysteria, and neuralgic headaches are often greatly relieved, as also hypochondriasis, and debility after recent illness or hard work, convalescence from acute pulmonary attacks and notably hooping-cough. Disordered menstruation is benefited; also chronic bronchitis and even asthma, where there is no emphysema. Phthisis in its early stages is cured by mountain climate, Dr. Lombard thinks, by the generation of emphysema, which causes the compression and obliteration of the vessels from which hæmoptysis proceeds, and also by the pressure of the lung-vesicles facilitating the absorption and removal of morbid products. In its advanced stages, very few writers recommend a mountain climate for phthisical patients, nor does our author.

Hæmorrhoidal congestion, scrofula, and goitre, all profit by a mountain climate. Diarrhœas not connected with organic mischief are often cured, with the aid of a careful diet, but scarcely, if there be ulceration of the bowels or affection of the liver.

Organic diseases of the heart or of the large blood-vessels are positive contraindications to mountain climate.

Such is an abstract of a work, in which the most striking views laid down are, the existence of a sub-alpine zone, in which both phthisis and scrofula are more common than lower down, or higher up, and the belief that phthisis is cured by the production of emphysema. As to the physiological effects of mountain air, there is only given a digest of the results of the observations of others.

It is to be hoped that the Indian medical service, though doing much in other branches of medicine, may find time to respond cordially to the reference, which, we understand, has been made to them by the Indian government. They might supply valuable information, and supplement that which has been furnished by their French brethren.

J. MACPHERSON, M.D.

A System of Midwifery, including the Diseases of Pregnancy and the Puerperal State. By WILLIAM LEISHMAN, M.D., Regius Professor of Midwifery in the University of Glasgow, &c., pp. 835. Glasgow: J. Maclehose, 1873.

Dr. Leishman, well known to the obstetric student through valuable monographs on various subjects, particularly his philosophical and masterly essay on the *Mechanism of Labour*, now appears before us as the author of a voluminous, well-arranged, and thoroughly practical text-book on the subject of midwifery. Dr. Leishman's *System of Midwifery* is profusely illustrated, and contains a fair representation of the views entertained by the most esteemed writers and teachers of the present day. The style is good, and the printing excellent.

In a work of this kind, it is difficult perhaps to avoid the extremes of superfluous citations of authorities and a too dogmatic treatment of the subject; both extremes are bad. Dr. Leishman's work might perhaps have been a trifle more dogmatic, but that it is not, is hardly a fault. The real student of a subject is fond of a big book, and will prefer one that will assist him in going to the root of the matter to a mere *précis* of the subject.

It is impossible in this notice to allude to more than a few points in detail. Dr. Leishman advocates, we think wisely, the employment of the straight in preference to the curved forceps in ordinary cases, the straight instrument being more easily applied, and being applicable to all but a few cases. Dr. Leishman believes, we are glad to see, in the efficiency of the binder. On another point, also very important in reference to the after-treatment of the puerperal patient, he is equally positive, viz., his disapproval of the practice which long prevailed, but is now happily passing away, of depriving the patient of her usual food during the first three or four days immediately following the labour.

In criticising the various methods of inducing premature labour, we think the 'rupture of the membranes' is hardly treated by Dr. Leishman with proper consideration. In many cases we believe it by far the best of the methods available; although undoubtedly, where time is an object, the dilatation of the cervix by hydrostatic pressure is preferable, inasmuch as it both excites uterine action and accomplishes a portion of the work which has to be done.

The treatment of retention of the placenta in cases of early abortion, attended with hæmorrhage, is a subject of interest. Dr. Leishman appears to prefer leaving the placenta to be expelled by natural efforts, unless the os is pretty well dilated, trusting meanwhile to the plug. Like all practical men, he prefers the fingers to any other instrument for removing the placenta under such circumstances. Upon the treatment of cases of *post partum* hæmorrhage by application of perchloride of iron to the interior of the uterus, Dr. Leishman pronounces no very definite opinion. He states that this procedure 'was originally used by D'Outrepoint and also by Kiwisch,

who, upwards of twenty-five years ago, strongly supported this method of treatment.' Adverting to the objections urged to this remedy, he says: 'We do not wish in any way to undervalue their objections; but even admitting their validity, and viewing the operation in the light of a desperate remedy, the facts which are given by Kiwisch, and recently in this country by Dr. Barnes, are such as to afford us much encouragement, and may warrant us, under certain conditions, in availing ourselves of this method of treatment.' Whether the remedy be finally accepted by the profession or not, it is probable that good will result from the discussions elicited on the subject, and the greater attention which will in future be paid to the prevention of *post partum* hæmorrhage. There are good reasons for concluding that, when proper preventive treatment is carried out, the occasions for the perchloride injections will be very few and far between.

On the management of the infant during the month, a subject too generally slurred over in similar text-books, Dr. Leishman has a satisfactory practical chapter. The subject of puerperal fever is discussed by Dr. Leishman at some length. He apparently adopts—though with limitations—the zymotic, to the too great exclusion, as we think at least, of the pyæmic theory of puerperal fever. We believe that professional opinion is more and more inclining to the conclusion that in puerperal fever we have an affection which is, in one form or other, a pyæmia, commencing at the internal surface of the generative organs. We need not dwell on the importance of the corollaries which result from this latter view of the matter, particularly in reference to the preventive treatment of a disease which, when once thoroughly established, has hitherto proved very unsatisfactory to deal with.

Ignipuncture. Its Different Uses, and its Special Indication for White Swellings. By DR. TRASSENARD. 8vo. Paris: A. Delahaye, 1873.

In this inaugural thesis, Dr. Trassenard describes a mode of treatment much employed by Professor Richet. He explains in successive chapters the mode of proceeding, the pathological physiology of ignipuncture, and then reviews the various affections on which it is employed by M. Richet, and explains its indications and counter-indications. The thesis is one worthy of being consulted.

MISCELLANY.

LADY DOCTORS IN GREAT BRITAIN.—A considerable step has been made by the King and Queen's College of Physicians of Ireland towards the licensing of the practice of midwifery by ladies in this country by a registrable diploma. This college holds a charter, dated 1692, which was specially granted to it for the purpose of examining and licensing midwives, and punishing those who were not licensed. It has, however, in the course of a hundred years, licensed two only, and has used for men exclusively the powers granted in behalf of women. It has now been applied to in behalf of women, and has expressed its willingness to fulfil the terms of its charter, and having passed a resolution admitting the principle, has also appointed 'a committee to report to the college on the qualification and examination to be adopted in the case of candidate midwives, and the form of the diploma to be conferred on them.'

THE UNIVERSITY OF WÜRZBURG, a notice of which was given in the MEDICAL RECORD of December 24, is about

to receive a valuable addition to its staff in the person of Professor Rindfleisch, of Bonn, the author of a work of high merit on Pathological Anatomy, well known to English readers through its translation by the New Sydenham Society. He has been appointed Professor of the subject on which he has so ably written, in the Würzburg University; and Professor Klebs, who has hitherto held the post, goes to the University of Prague.

THE RIBERI PRIZE.—The following are the conditions of the fifth competition for the Riberi prize of 20,000 lire (800*l.*); the subject of which is 'the Pathology of the Female Generative Organs.' 1. Complete treatises and monographs are admitted to competition; 2. The works, written in legible characters or printed, must be presented in the Italian, Latin, or French language, and will become the property of the Royal Academy of Medicine of Turin; 3. Printed works must have been published in 1874, 1875, or 1876; two copies must be sent post free; 4. The essays in competition, written or printed, must be sent to the Royal Academy of Medicine in Turin before Dec. 31, 1876.

THE AMSTERDAM MEDICAL CLUB has agreed on the following tariff of fees from January 1.—For ordinary visits, 2, 1'50, 1, and 0'60 florins; for vaccination, 10, 5, and 3 florins; for subcutaneous injection, 3, 2, 1'50, and 0'75 florins; for visits in the country, in addition to travelling expenses, 5 and 3 florins per hour. (The Dutch florin is = 2*s.* 11*d.*).

A NEW hospital, constructed on the most modern and sanitary principles, is about to be built in the grounds belonging to the hospital of Santo Antonio in Oporto.

PROFESSOR TRAUBE, on the 25th of last month, completed his twenty-fifth year of office as directing physician of the Charité Hospital in Berlin. Congratulatory addresses from his colleagues, pupils, and friends, were presented to him; and in the evening he was entertained by the directors and staff of the hospital at a dinner, at which eighty persons were present.

THE session of the Medical Society of Lisbon was opened on January 10. The president, Dr. Arantes Pedrosa, delivered an excellent address on the value of hygiene, and pointed out in plain terms the necessity existing for sanitary improvements in the Portuguese capital.

DR. RADZIEJEWSKI, *privat docent* in the University of Berlin, a young physician of great promise, has died suddenly of apoplexy.

CHOLERA occurred in 61 fresh cases in Munich, and caused 36 deaths, on January 21, 22, and 23.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 17*s.* 4*d.*; free by post, 19*s.* 6*d.*

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19*s.* 6*d.* Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, FEBRUARY 11, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

CLINICAL MEDICINE.

ON THE TREATMENT OF DISEASES OF THE STOMACH. BY PROFESSOR W. O. LEUBE, OF JENA.*

(Concluded from p. 66.)

In proceeding to speak of the treatment of dyspepsia, Dr. Leube says that he has purposely passed over the more deeply seated diseases of the stomach, such as ulcer, cancer, &c.; and that it is not his intention to enter into any details as to the medicinal remedies, sufficient information regarding which will be found in all text-books. Regarding mineral waters, he says that much remains to be done by statistics and experiments before it can be absolutely determined what water will best suit each form of dyspepsia.

He proceeds to comment at length on the dietetic treatment of gastric disorders.

In presenting dietetic rules, he says, I believe that the first principle to be laid down is, that there is decidedly no better diet for a sick stomach than rest.

We obtain perfect rest for the organ only when the food is given, not in the usual way by the mouth, but *per anum*. It has been proved by physiological experiment and by clinical observation, that the use of clysters of meat and pancreatic fluid, as recommended by me, is the means of introducing a considerable quantity of nitrogen into the body, so that in this way a man can be nourished for a long time, and that the feeling of hunger is allayed; and hence the employment of this method is indicated in the most severe forms of stomach-disease. Thus, without detriment to the general nutrition of the patient, the stomach may be relieved of the irritation produced by food, and the diseased process in the mucous membrane may come to a natural end; and further, the advantage is gained, that the medicines administered internally can act with more effect on the inner surface of the stomach than when they are mixed with more or less chyme, and come into contact with the disordered mucous membrane in a state of dilution or chemically changed.

In most cases of stomach-disease, however, it is not necessary to entirely suspend the action of the organ; we gain our object much more completely by allowing the patient an easily digestible diet—provided that this diet is really easy of digestion.

Here we meet with the question which every day forces itself on us at the bed-side, but which it is difficult to answer:—What diet corresponds to the idea of 'easily digestible'? Let us honestly confess that this question has often perplexed us, because on the one hand we feel that in its correct answer lies the central point of the whole treatment of the disease under consideration, and on the other hand we cannot always suppress our own doubt as to the success of our prescription, when we describe this or that diet as easy of digestion. We should not, however, be ashamed of this doubt; for really demonstrative experiments have not been made in this chapter of physiology, at least on an extensive scale. Dr. Leube refers to the experiments made a century ago by Gosse, who had the exceptional power of emptying his stomach by swallowing air, and who observed the changes produced in food at various intervals of time; and to the observations of Spallanzani, Beaumont, Frerichs, Busch, Kühne, &c.

In a stomach-patient it is not altogether desirable that all the food in the stomach should be utilised; for those articles which undergo little change, and pass out of the stomach quickly, so far as they do not produce mechanical irritation, give much less trouble to the diseased organ than those which are readily acted on by the gastric juice, and hence remain longer in the stomach and severely test its impaired powers. In considering the question of the digestibility of food in any given case, the nature of the disease, the individuality and the constitution of the patient, must be taken into account.

In a scientific and physiological sense, the question of the digestibility of different kinds of food is on the whole still unsolved. But we must not therefore abstain from giving our patients directions as to the choice of diet.

Of the different kinds of meat, young veal, fowl, and pigeons are digested with least difficulty. With many persons, fish and beef must be placed in the same category; and it is advised to give the former to the patient in the boiled state only, while beef is recommended to be brought to the table roasted, but retaining a red colour. It is an old culinary observation, that excessive roasting and boiling both render meat tough; and, in accordance with this, the latest published researches of Fick have shown that the same digestive juice requires three times as long to act on boiled meat as on raw. In the use of roast meat, it is an established rule, even among the non-professional public, to abstain from the addition of fatty sauces—a rule which finds its justification in the fact that pieces of meat enveloped in fat are less readily acted on by the gastric juice than are pieces of lean meat.

The experience of thousands of years has proved milk and eggs to belong to the class of easily digestible substances. Milk is naturally borne well by many persons suffering from gastric disease, as all must have observed; and raw eggs are said to give but little trouble to the stomach. This latter statement, however, is not confirmed by Dr. Leube, who has found boiled eggs more digestible than raw; and Fick's most recent observations show also that raw albumen has no advantage as regards digestibility. Dr. Leube allows his patients to use only soft boiled eggs.

Of vegetables, the most tender only are to be allowed; such as asparagus, young hops, shelled sugar-peas, and young carrots. Potatoes should never be eaten except in the form of *purée*. Gruel,

* Extracts from a paper read before the fifth meeting of the Thuringian Medical Association at Muhlhausen. (Volkmann's *Sammlung Klinischen Vorträge*, no. 62.)

containing particles of groats which may irritate the stomach, is specially to be avoided.

The bread should be wheaten, and absorbs the gastric juice better if it have been baked for some time.

I avoid alcoholic liquors, says Dr. Leube, as much as possible in gastric diseases. If the use of wine be urgently desired, it may be given to the patient equally well (as is the custom in England) *per anum* as by the mouth.

Although the use of the diet above described will be followed by good results in many cases of stomach-disease, there are yet very many cases in which, though easily digestible, it is not borne by the patient; and the question arises, what diet is more easily digestible. It is obvious that our object would be gained if we could prescribe a diet which, while possessing the highest nutritive properties, would give the least labour to the diseased stomach. These conditions are most completely met by the peptones themselves, which are formed from the albuminous matters taken into the stomach and are readily absorbed. But their preparation is attended with great technical difficulties, as it requires, besides the mixture of pepsin and acid, a temperature of 104° Fahr. to be maintained all the day long. Besides, a tolerably large experience has taught us that all solutions made with the natural ferment have such a disgusting smell of vomited matters, that I cannot persuade patients to use them. For about a year, in conjunction with my friend J. Rosenthal, of Erlangen, I have endeavoured to bring meat, under the influence of heat and acid in air-tight vessels, into a state of peptonisation, which will be completed by the pepsin in the human body, even at a lower temperature. Under the influence of the above-mentioned agents, meat forms a very fine emulsion containing more or less peptone. Whether the amount of pepsin be high or low, this solution of meat has been proved by abundant observation to be the most unirritating and nutritious of all preparations of meat, and is borne well even in cases of the most obstinate vomiting. Its advantages are the following.

1. It is soft in consistence, like an emulsion; and thus it does not produce the irritation of the mucous membrane which other articles of food do by their friction on the walls of the stomach. This quality especially fits it for cases of gastric ulcer, inasmuch as all harsh contact with the ulcerated surface is avoided; and this becomes evident from the fact that the cardialgic pains cease in patients with gastric ulcer from the day when they commence the use of the solution of meat. In treating patients with this affection, my method is as follows. I keep the patient in bed two or three weeks, and apply to the epigastric region hot poultices by day, and a Priessnitz's wrapper by night; and I allow him to eat nothing but a pot of the solution of meat (equal to half-a-pound of beef) daily, and two pipkins of milk, with finely powdered biscuit soaked in it. Under the use of this diet, the patients almost uniformly improve rapidly; the vomiting ceases, the pain disappears, and even deep pressure on the epigastrium from day to day becomes less painful. After two or three weeks, I proceed carefully to more solid food, assuming that the healing of the ulcer has sufficiently advanced; but naturally, the digestion of such food only as has been above described as easily digestible, will be as yet expected from the sick stomach.

2. The taste of the preparation reminds one of Liebig's extract of meat, but it is much duller. I

give it either pure, in ice or with meat-broth, or I add a little of Liebig's extract to it, to heighten the taste. It is very readily taken by the patients: but it cannot be denied that in some cases, after using it for a long time, they begin to feel a repugnance to it. This, however, is not the fault of the preparation, but arises from our habit of changing our articles of diet. Who would not become disgusted with boiled beef, for instance, if he had to eat it morning, noon, and night, for weeks together?

3. The remarkable nutritiousness of the solution of meat depends on the fact that all the constituents of flesh—nitrogen, salts, &c., are contained in the preparation. It thus cannot be compared with Liebig's extract of meat, the direct nutritious value of which is not in the present day rated highly by anyone.

4. The easy digestibility of the preparation cannot be doubted, from its consistence, and from its being prepared for digestion by treatment by heat and hydrochloric acid. The question of nutritiveness and digestibility, however, can only be settled by experiments on animals, and by quantitative determination of the amount of nitrogenous matters in the excreta of persons living exclusively on the solution of meat. Dr. Leube is engaged in carrying out researches of this kind.

5. The preparation will keep well if sufficient care be taken in the manufacture. While using it, I am in the habit of keeping the pot in iced water, in order to prevent it from spoiling.

The range of diseases in which the solution of meat is usefully indicated, is evidently not only the limited one of gastric disorders. Wherever we have to introduce an absolutely non-irritant food into the stomach, and where danger is threatened through the ingesta by overworking the intestinal canal or mechanically irritating its walls, the use of the solution of meat is indicated. I call to your minds typhus [the author evidently means typhoid or enteric fever], dysentery, tuberculous ulcers of the intestines, peritonitis, &c.; also hæmorrhage from the stomach and intestines—in which, however, clysters of meat and pancreas may be administered *per anum* with still less danger.

EPIDEMIOLOGY.

ON THE ETIOLOGY OF TYPHUS FEVER, FROM OBSERVATIONS ON THE BERLIN EPIDEMIC OF 1873. BY PROFESSOR ZUELZER.*

Since the great epidemic of petechial typhus in 1867, which I have already described,† Berlin has been attacked by this disease to some extent. Virchow‡ reported on the cases which occurred in the Charité Hospital in 1871; and Obermeier§ on a portion of the cases in 1873. In my department of the Charité Hospital, the first cases of the disease appeared in the beginning of February, 1873; and up to the end of the epidemic I had altogether

‡ *Archiv für Pathologischen Anatomie*, vol. liii.

§ *Berliner Klinische Wochenschrift*, 1873, p. 349.

169 male and 31 female patients under treatment. Although the observations on these cases, which I have already in part communicated to the Hufeland Society, will be published as a whole in a larger treatise on acute infectious diseases, certain of the individual results at which I have arrived appear to me to possess an interest for public hygiene, and I will therefore here set forth some of them.

The social conditions of the winter 1872-73 are fresh in our memory. There was abundant employment for the labouring classes; and the increase of wages corresponded completely with the increased price of provisions. In spite of this, all action was often and for a long time hindered in many industrial circles by the numerous strikes. In consequence of the forced interruption of labour, as a rule, the unmarried workmen wandered from many of the larger towns, and the married ones were obliged to be idle and to stint themselves to the utmost in the interval of destitution.

As the next result of this abnormal condition (I must here, in the want of other materials, limit myself to the observations which I had an opportunity of making in my department of the Charité Hospital) relapsing fever broke out anew in November, 1872. It reached its highest point in December and January, and lasted till March. In the beginning of January, the first cases of petechial typhus appeared. In a short time, the disease spread remarkably; although a public lazaretto was provided for the patients, there came into my wards in February fourteen cases, in March sixty-three, and in April eighty-four. That only thirty cases were admitted in May, and nine in June, was not due to the diminution of the epidemic, but to a special regulation of the authorities, in consequence of which patients, who could be moved, were carried to the town lazaretto.

This is not the place to discuss in detail the question of the spontaneous development of typhus in connection with the social conditions that have been described. I will only mention that, with regard to the mutual sequence of typhus and relapsing fever, that which has often been observed was repeated here. First, relapsing fever prevailed alone among certain circles of the population: when it was at its height, typhus appeared, and advanced concurrently with the other for some time, until, in the spring and summer, it entirely gained the upper hand, the relapsing fever having disappeared. In the time referred to, it was interesting to note this sequence in the patients admitted into the Charité. There is here a regulation, that the homeless poor may voluntarily report themselves to the police; by the latter they are lodged in certain rooms of the police station and other institutions, and the sick are sent to the Charité; the homeless poor found by the police are treated in the same way. In the time following December, 1872, the number of sick among the homeless so greatly increased, that frequently two or three waggons in a day came to the hospital with more than twenty—sometimes even thirty—patients. In the first week, with the exception of a relatively small number of ordinary cases, they were exclusively cases of relapsing fever that were brought; next month, scattered cases of petechial typhus were mixed with them; and later on, the police waggons brought cases of the latter disease, with only a few exceptional cases of relapsing fever. Very soon, however, the patients were no longer recruited from the homeless, but also from the prison-houses of Berlin, into which the epidemic had been introduced.

A waggon full of thoroughly depressed, dirty men, in a high state of fever, and often in a state of somnolence, affords a sufficiently horrible illustration of many of our social arrangements. How far the long transport, especially in vehicles not fitted for the purpose, is injurious to typhus patients, will be discussed hereafter in connection with clinical observation.

The disease, as has been said, limited itself at first entirely to those thoroughly destitute individuals technically designated 'tramps'—people without employment, unable to earn the means of support, wandering from place to place, and subjected to all kinds of want. Three or four of my patients, along with ten or twelve others, after enjoying the benefit of the asylum for the homeless to the greatest possible extent, had assembled, in the absence of any other shelter, in a shed in the Müllerstrasse, and had spent several nights there; here they were attacked with the disease and were brought to the Charité. Another similar number of patients attributed their disease to their frequent lodging at night in an empty warehouse in the Prenzlauerstrasse, where, with thirty or forty houseless persons, they found a refuge. Two patients stated that they received the infection in the asylum for the homeless.

Next after these came various groups from the so called *pennen*—lodging-houses of the lowest class, where a price, however small, is paid for a night's accommodation. Nine cases had lodged in the 'Deutsches Verkehr' (Old Jakobstrasse, no. 66). This lodging-house comprises three moderate-sized cellars and three somewhat smaller rooms on the ground floor; these rooms served to lodge a hundred or a hundred and fifty men, often more. The dirt of the rooms and the smell of the air were very great. I have made observations on the spot, which there is not space to relate here. Similar conditions existed in another lodging-house (32 Müllerstrasse) where sixty or eighty persons spent the night: of these, five were brought to the Charité with typhus fever.

Besides these, similar groups of cases came to the hospital from the so-called Christian lodging-houses in Auguststrasse and Oranienstrasse, and, as has already been said, from the Berlin prisons. There were also a number of single cases among the persons living in the immediate neighbourhood of the lodging-houses, who had probably got the disease from them. Several of the patients had had intercourse with the sick in the discharge of their official duties.

Cases also arose in the hospital itself. A large number of persons who had been brought to the Charité with other diseases, fell sick of typhus fever after having been in direct or indirect intercourse with cases of the disease. I alone have had under my notice nine convalescents from relapsing, and two from enteric fever, as well as several cases of pneumonia and other inflammatory diseases and of mental disease, who were seized with the prevailing epidemic.

Besides these, the disease attacked ten male and four female attendants, five of the former and two of the latter being in my department, where it was at last found necessary to engage convalescents as attendants. Of the medical staff, the assistant-physician of the first medical clinic (the late Dr. Bock) and three subassistant physicians, were attacked. Of especial importance in regard to the etiology of the diseases, are the cases of a hospital laundress who

washed the patient's clothes, of a watcher of the dead bodies, and of a labourer in the churchyard of the Charité. According to the assertions of these three persons, which is confirmed by the position of their dwellings and the nature of their employments, none of them had come into contact with our patients.

Such is a sketch of the course and spread of the epidemic as I observed it. While in 1867 I had the opportunity of ascertaining the spontaneous development of the disease in certain localities, I could in the present case obtain no information on this matter. On the other hand, the whole course of the epidemic, the occurrence of cases of this disease in single groups, or more frequently in a certain sequence, and its introduction into the prisons and the Charité, speak incontestably in favour of its great contagiousness.

In most of my cases, the communication of the fever was direct; the persons infected had come into direct contact with the sick. In most cases, a stay of some duration in rooms containing fever-patients seems necessary for infections; the infection was with special frequency imputed to the use of the same dormitories (as in the asylum for the homeless, the lodging-houses, prisons, &c.). Two of my hospital attendants, who had separate sleeping-rooms, escaped the disease; while the rest, who slept in the wards (even in the hospital barracks) were attacked. In single cases only (as in public officials) was a transient communication with the sick sufficient for infection.

It follows without doubt, that the diffusion of the agent producing the disease takes place entirely through the air; the assumption that it may also be carried by some other vehicle, as drinking-water, food, &c., cannot be proved. Through the air, the poison is carried over a rather wide extent; for instance, several cases occurred in the first story of one of the hospital buildings, in which the infection could only be traced to the patients in the ground-floor, inasmuch as all communication, direct or indirect, was entirely cut off. The reception of the poison by the healthy, seems probably to take place only through the respiratory organs.

The starting-point of the poison appears in many cases to be the expired air from the patients. It was, however, in a good number of cases communicated from the surface of the body; and this view is favoured by the fact of its communication at second-hand, in the case of the laundress who washed the patients' linen. We have already repeatedly observed similar cases, and Murchison adduces several analogous instances in his *Treatise on the Continued Fevers*. Murchison also describes some cases belonging to this category, of which the most important is his own illness from infection in the *post mortem* room.

These examples, the number of which may be increased by a closer investigation of the subject, appear to me to possess a certain importance, inasmuch as, in the case of small-pox and some other infectious diseases, they indicate that the morbid poison may retain its activity independently of the vital processes of the human organism.

With these cases is intimately connected the question as to the stage of the disease in which typhus is most contagious. According to my observations, very many cases of infection are traceable to patients, in whom, from the middle of the second week of the disease onwards, abundant desquamation takes

place either in branny particles or in larger patches. In this stage, when almost free from fever, several cases came into the prisons and hospitals here, and rapidly spread the fever.

In the next place, the blood seems to me to be highly infectious. In the absence of observations on man, I have inoculated ten rabbits with blood from patients in various stages of typhus. Seven of these animals, into which I subcutaneously injected blood from patients in the height of the fever, in the proportions of about half-a-drachm to a moderate-sized animal, died within three or four days; three rabbits, into which I injected blood taken from patients after the crisis had set in, remained intact. The *post mortem* appearances were on the whole negative; in two cases I found pneumonic foci, besides hyperæmia of the lungs, kidneys, &c.

As the experiments here mentioned might be regarded as imperfect, I consider it important to institute further and more extended researches on the subject, believing that a more consistent principle of classification for the so-called infectious diseases might be obtained from the results of inoculation than from vague notions on infection, contagion, miasma, &c. It is probably to the great confusion which prevails as to these terms, that the frequently contradictory results of observations made on different epidemics in different places are to be attributed.

A few words in conclusion on what is usually called 'personal predisposition.' Robinski, in his *Law of the Origin and Spread of Contagious Diseases*, has very ably criticised the numerous obscurities which have crept into the treatment of this subject. In regard to petechial typhus he expresses the opinion, derived from the observations of an epidemic at Tylitz in East Prussia, that predisposition to the disease is established by certain external injurious influences independently of previous conditions of the organism; thus, in Tylitz, those persons only took the disease through contagion, who had drawn their drinking-water from certain foul springs. The instances related, and the course of the Berlin epidemics in 1867 and 1873, do not support this idea. The manner in which the disease spreads, first seeking its victims among the lowest and most destitute stratum of the population, and then attacking those in better circumstances (medical men, public officials, etc.) as soon as they come into contact with the sick, indicates that the contagion may develop its activity in spite of the most various individual conditions. The poison seizes on every one who comes within the circle of its action, provided that he be exposed to it for a sufficient time, just as is the case with certain poisons that are gaseous or are suspended in the air. I will speak hereafter of the predisposition acquired through certain fixed personal conditions, as of age and sex, and of the application of these observations to hygiene.

ANATOMY AND PHYSIOLOGY.

PASCHUTIN AND EMMINGHAUS ON THE SECRETION OF LYMPH.—Tomsa, in his experiments upon this subject, collected the lymph from the testicle; but the quantity so obtained is by far too small to admit of exact observations being made. The researches of Hammarsten and Genersich have already shown that a plentiful supply of lymph can be

obtained from the isolated brachial trunk. Paschutin (*Arbeiten aus der Physiol. Anstalt zu Leipzig*, vol. vii.) selected the fore-limb of the dog for his experiments, partly because of the large quantity of lymph which can be obtained, and partly because the rootlets of the lymph-vessels arise here only in skin and muscle, so that the lymph obtained is not a mixture secreted by many different tissues, as would be the case if it were taken from the cervical trunk or from the thoracic duct. Further section and stimulation of the nerves and changes in the condition of the circulation can easily be produced in the area from which the lymph is obtained.

Genersich and Lesser have already shown that lymph is only poured out from the limbs, when these are either passively or actively moved. For a description of the manner in which the limb was moved, and for other details, we must refer to the original. For comparison, the lymph-vessels were emptied as far as possible by stroking the limb with the hand, before each period of the experiment.

1. With regard to the medium rapidity of outflow of lymph, Paschutin found that in all cases, with the duration of the experiment, the outflow of lymph was diminished, as long as the animal was kept under the same conditions. The lymph which flowed out on movement of the limb, was not derived from a store previously prepared in the tissues, but was actually secreted during the time of movement. With regard to the diminution of the rapidity of the outflow of the lymph, that was not due to exhaustion of the secreting apparatus; for, after the limb had been allowed to rest for a long time, no more lymph was obtained on resuming the pumping movement, than flowed out before the period of rest.

When the dog was poisoned with curare, the rapidity of secretion increased and reached its maximum in from 40 to 50 minutes, and then gradually diminished. The initial increase did not depend upon section of the spinal cord or brachial plexus, nor did the increase and decrease in the rapidity run parallel with the arterial blood pressure. One of the most striking results of these experiments was, that changes in the arterial blood-pressure had no effect on the excretion of lymph.

To determine the effects of temperature on the secretion of lymph, and to ascertain if the cooling which the animal underwent during the experiment, was the cause of the diminution of outflow, the animal was placed in a double-walled box, capable of being heated and kept at a constant temperature. The lowering of the temperature was not the cause of the diminution of the rapidity of outflow. On raising the temperature several degrees, the secretion was increased as long as the spinal cord was intact; but not so after its section.

2. Regarding the percentage composition of the lymph-serum in fixed residue, viz., albumen, in 84 different observations on lymph taken from different animals, and from the same animal at different times, the percentage composition of the lymph-serum clearly changed. The residue varied from 2.61 to 6.55 per cent. It increased with duration of the experiment, and became less when the absolute quantity of lymph increased. Similar results were obtained by Genersich on passing defibrinated blood artificially through surviving extremities. When in curarised animals, in consequence of any cause, the rapidity of outflow was increased, then the same proportions, with regard to the solid residue of the lymph, occurred just as in non-curarised animals,

but not with quite the same regularity. The lymph was sometimes tinted red with blood-corpuscles; nevertheless, in this case, the author was not able to find that the serum contained more albumen. In the first period of the action of curare, in which the amount of fixed constituents had clearly increased, the lymph was clearer than usual. The changes in the composition of the lymph afford an additional argument that the lymph is actually secreted during the time of observation.

H. Emminghaus (*Berichte der K. K. Gesellschaft der Wissenschaften, Math.-phys. Classe*) has studied the dependence of the secretion of lymph on the blood-current. In this case, the hind foot of the dog was employed, and the lymph-vessels were emptied artificially by the hand. No lymph flowed out generally, when the foot was quiet and at rest, in animals poisoned with opium, a fact already pointed out by Paschutin. [I have been able to verify this fact on non-poisoned animals.—*Rep.*] Section of the vaso-motor nerves produced no diminution in the secretion of lymph. In animals in which the sciatic nerve had been cut through, on ligature of the veins of the limb, the lymph flowed out more richly than before; and when the veins were kept tied, the quantity of lymph was from four to six times greater than before the ligature of the veins. Here swelling of the foot was observed. During ligature of the veins, spontaneous outflow of lymph was often observed. On removal of the ligatures, the after-effect of the stagnation showed itself in the increased excretion, for an hour or more. Not only did the lymph vary in quantity during ligature of the veins, but also in percentage composition and in colour. In normal experiments the lymph was generally clear; when the veins were tied, the colour became deeper red with the duration of the ligaturing. The percentage composition of the serum (in albumen as in Paschutin's experiments) diminished in fixed constituents in lymph obtained from limbs with the nerves divided and the veins tied. Ligature of the veins without previous section of the nerves increased the formation of lymph, but still only in a moderate degree.

From his experiments, Emminghaus concludes that obstruction to the outflow of blood from the limb is of much greater significance for the excretion of lymph than changes in the strength of the arterial current; and further that, when the limb is so placed that there is no hindrance to the outflow of blood from the veins, little or probably no lymph is secreted. New lymph, however, is formed immediately, either when the elastic equilibrium of the tissues is disturbed, or when any obstruction is offered to the outflow of the venous blood.

SOLUCHA ON THE FUNCTIONS OF THE SEMI-CIRCULAR CANALS.—Solucha has made experiments on this subject under Cyon's directions (*Pflüger's Archiv*, vol. viii.). The results obtained by Florens are already well known. Goltz ascribes the disturbance of movement produced by section of these organs, to the loss of the feeling of equilibrium; while Löwenberg regards the collective disturbance of movement as only consequences of a reflex stimulation of the nerves, which run in the membranous canals. The first point investigated by Solucha was, how far is an abnormal position of the head able to disturb the feeling of equilibrium of the animal, and so to produce the abnormal movements? The author confirms the experiment of Longet that mere section of the recti capitis postici majores et minores in the

dog renders the movements of the animal uncertain and insecure; the dog was unsteady on its feet, moved from side to side, kept the fore feet widely apart from each other, running was rendered difficult, &c. After five or six days the head generally assumed the normal position, and at the same time the walking became normal.

In a second series of experiments the author sought to give pigeons a peculiar position of the head, without wounding important parts—a position such as occurs on section of the canals, with the beak directed upwards, and the occiput towards the ground. On fixing the head to the breast in this position with a thread, the animals conducted themselves partly like those in which the horizontal as well as the vertical semicircular canals were destroyed. They could not retain their equilibrium, but moved to and fro on their legs, and always sought for a third point of support, made movements *de manège*, &c. As soon as the head was freed, the whole disturbance of movement disappeared, and locomotion became normal. This experiment also shows the importance of a normal position of the head, so that the animal can be able to preserve its position of equilibrium, as well as to execute co-ordinated movements.

In what way is the feeling of equilibrium dependant on a normal position of the head? The answer to this is, for the greatest part, to be sought in the changes which our conceptions of the position and distance of outer objects bear in relation to our own body. In pigeons, provided with spectacles with prismatic glasses, which produced artificial strabismus, disturbance of movement distinctly analogous to the higher degrees of that which occurs after section of the semicircular canals was observed. In some cases even 'pendulum movements,' corresponding to those seen on section of the horizontal canals, were noted. On section of one horizontal canal, the animal made several lateral movements of the head, beginning from the injured side, which soon ceased. On section of the corresponding canal on the opposite side 'pendulum movements' of the head occurred, and persisted very long. The violence of the movement increased from the beginning onwards, until they reached a maximum, when the animal lost its equilibrium, fell over, executed movements *de manège*, &c. In a few cases the animals recovered completely, but generally after four or five days the animal was found in a corner with the peculiar position of the head above described, and quite quiet, but when disturbed it resumed the pendulum movements, &c. Most of the animals died in from ten to twenty days. On section, the neighbouring parts of the skull were bloody and infiltrated, and the cerebellum was softened on the posterior surface and of a yellowish-green colour. The results of section of the smaller vertical canals were in some respects similar to the above, but differed in some important points. In section of the horizontal canals, the head moved in a horizontal plane from right to left, and back again; but in animals with cut vertical canals, the pendulum movements of the head occurred from above downwards and back again—then in a vertical plane. The subsequent movements of the trunk were also different, in that the whole trunk tumbled round on its transverse axis, and that mostly from before backwards.

On section of all four canals, violent movement of the head, resembling a screw motion, occurred immediately, accompanied by general swinging movement of the whole body.

That disturbance of equilibrium is a direct consequence of section of the semicircular canals is certain. 1. These disturbances occur immediately after the operation, and this when it is free from all other complications, as section of muscles, bleeding, injury to the cerebellum, &c. 2. The two sorts of movement, as well of the head as of the trunk, scarcely admit of a doubt, that the semicircular canals stand in relation to certain conceptions of space, and sensation. By means of the nerves which end in the membranous canals, a series of unconscious impressions are continually communicated, which lead to unconscious conclusions as to the position of the head in space. The semicircular canals contribute only indirectly to the retention of the equilibrium of our body, in that they direct the position of the head in space.

The chief results of these experiments are the following. 1. For retention of equilibrium, it is necessary that the animal has correct conceptions as to the position of its head. 2. The semicircular canals possess the functions of informing the animal, by a series of unconscious (auditory?) impressions, as to the position of his head in space, and each semicircular canal has an exact relation to a dimension of space. 3. The movements which occur after section of the semicircular canals are of three sorts: *a.* Disturbance in equilibrium, as the direct consequence of the injury; *b.* Swinging movements, as consequences of stimulations arising from abnormal auditory sensations; *c.* Consecutive phenomena, produced by inflammation of the cerebellum, occurring several days after the injury.

PRÉVOST ON THE FUNCTIONS OF THE LINGUAL NERVE.—Prévost (*Archives de Physiologie*, vol. v. pp. 253 and 375) has arrived at the following conclusions. 1. Ablation of both sphenopalatine ganglia does not cause in dogs and cats any sensible modification of the sense of taste in the parts supplied by the lingual nerve. 2. After section of the chorda tympani in dogs and cats, with cut glosso-pharyngei, the sense of taste was somewhat modified in certain cases, notably diminished in others, and completely abolished in one experiment. Prévost's experiments do not permit him to specify the part which the chorda tympani plays in relation to the function of taste, but he is inclined to accord to it only an accessory rôle. 3. Contrary to the old views of Vulpian and coinciding with the results of his recent researches, it is found that the chorda tympani carries fibres to the terminal branches of the lingual nerve as well as to the submaxillary gland. He has found, after section of the chorda in the cat, dog, rat, rabbit, and guinea-pig, degenerated nerve-fibres in the terminal branches of the lingual nerve, as well as in the mucous layer of the tongue and in the submaxillary gland. 4. The chorda tympani has not a trophic centre in the papillæ of the tongue; and if the submaxillary ganglion act on it as a trophic centre, this influence ought to be very limited. After section of the chorda tympani in the ear, the central end of this nerve (on the side of its facial emergence) remains healthy.

WILLIAM STIRLING, D.Sc., M.B.

BAUME ON THE ERUPTION OF THE TEETH.—Herr Robert Baume, writing on the eruption of the teeth (*Vierteljahrsschrift für Zahnheilkunde*) says that, according to his own observations, he cannot believe that the growth of the fang forces the tooth out of the alveolus. He inclines to the view that the eruption is due to changes in the alveolus; though

even on this point he is not prepared to agree entirely with other writers.

Herr Baume speaks in the first instance of permanent teeth in the lower jaw only, and afterwards brings forward evidence against the theory of apposition growth. 1. There may be lengthening of the tooth after the fangs are fully developed, in those cases where the antagonising teeth have been lost (that is, a tooth may be raised above the level of the adjoining teeth). 2. In cases of retarded eruption, the fang is fully developed in the body of the alveolus; and yet, when the mechanical obstruction to its eruption is removed, years after the fang has been formed,—the tooth takes its proper place in the jaw. 3. In some instances, the eruption of the teeth may take place without the fangs being developed, as in those cases where children are born with teeth already cut. Here, however, there may be as well, teeth with fairly developed fangs and crowns; but when the fangs are not developed, we generally find the crowns imperfect, so that their appearance conveys the impression that their eruption has occurred before they were fully formed and dentified. 4. Lastly, upper molars move forward in the jaw (from the posterior position which they occupy) before there is any trace of a fang, thus showing that the movement cannot be dependent upon the growth of the fang.

Baume next proceeds to show, by measurements of macerated jaws, that the apposition theory is not tenable. If a lower jaw be taken, from which the facial wall has been cut away, so that the permanent teeth may be seen in their places below the temporary set, it will be found that the measurement (in most cases) of the distance between the floor of the alveolar chamber in which the permanent tooth is placed, and the upper edge of the jaw, is 1·5 centimètres (6 inch). This would nearly correspond with the length of a fully developed fang (the same class of tooth being taken); but on eruption it is observed that, although the crown has travelled 15 centimètres before taking its position on the masticating level in the jaw, the fang has grown only a few millimètres; and the space between the first points of measurements, namely, the floor of the alveolus and the upper edge of the jaw, is filled up by the deposition of bony matter in the alveolus, and not by the further development of the fang (beyond the extent just mentioned).

Thus the length of the fang that is developed does not correspond with the distance that the crown has travelled; and these facts favour the view, that there is another influence at work causing eruption of the teeth than the growth of the fangs. Hermann (quoted by Baume) considers that the alveolus is narrower at the time immediately preceding eruption; but Baume considers that this is not the cause of the eruption, since the alveolus does not press upon the tooth. In fact, the space in the alveolus for the tooth is greater than is required for the crown and portion of the developed fang alone; so much so that, in a dried specimen of the jaw, the tooth is movable; and in the recent state it is but loosely held by its alveolar surroundings.

If the crown be through the gum, the hold which the alveolus has upon the neck of the tooth is very slight; but this space is less than it was immediately before the eruption. If the tooth be removed in this state, the alveolus will be found lined with a soft reddish tissue; which, when seen microscopically, will be recognised as formative matter. Beneath

this the alveolus may be felt, in some cases, roughened; and if a macerated jaw be taken, there will be found in the alveolar chamber a roughened and porous surface, broken through by many smaller and larger openings. The alveolus does not show the character of lamellæ, but points to the fact that here a very rapid development of bony tissue has taken place.

Baume attributes the development of this bone to the 'fibrous tissue' that lines the tooth-socket, and which not only rests on the surface of the alveolar chamber but pierces its walls. The author further considers that this 'fibrous tissue' is in intimate relation with the pulp of the growing tooth; and from the fact that this 'formative matter' is placed between the tooth and the walls of the alveolar chamber, he concludes that, on the one side, the eruption of the tooth is due to the growth of the formative matter, and on the other, that the rapid development of new bone within the socket is due to the presence of this same fibrous tissue. Hence, the narrowing of the bony alveolus is not the cause, but the consequence of the forward movement of the tooth, since the bony formation follows the space that is afforded by the eruption of the tooth. After criticising the views held by Tomes and Wedl, with regard to the development of the fangs and the growth of the jaw, the author explains why the first dentition is painful and the second dentition accomplished with but comparatively slight inconvenience (the wisdom-teeth only excepted). The main obstacle to the eruption of the deciduous teeth he considers to be the gum; and by the fact that the second teeth have as a rule no gum to pierce, he explains the ease with which their eruption occurs.

OAKEY COLES.

SMEE ON THE COAGULATION OF THE BLOOD.—Mr. Alfred Smeë (*Journal of Anatomy and Physiology*, June 1873) thus sums up his conclusions regarding the coagulation of blood. 1. The coagulation of fibrine is a physical act, and cannot be considered to be in any way identified with a vital property such as the contraction of muscular fibre. 2. The coagulation of fibrine depends upon and is regulated by the same laws which cause all insoluble colloid substances, whether organic or inorganic, to become pectous. 3. The soluble or fluid form of fibrine ought to be regarded as its allotropic form; and as in the case of its colloid analogue, silicic acid, its presence in the blood in the fluid condition depends upon the physical conditions under which fibrine is found in the living body.

T. LAUDER BRUNTON, M.D.

MEDICINE.

FREY ON TEMPORARY PARALYSIS IN CHILDREN AND ADULTS.—Dr. Anton Frey has published in the *Berliner Klinische Wochenschrift* for January 3, 10, and 17, a paper, founded on observations in Dr. Kussmaul's clinic at Freiburg, on temporary paralytic affections in adults, resembling the temporary spinal paralysis of children, proceeding apparently from myelitis of the anterior cornua.

After giving reasons for preferring the title of 'infantile paralysis' (Heine) to that of 'essential paralysis' (Rilliet and Barthez), the author describes the distinguishing features of the complaint. He main-

tains that the fundamental lesion is a very acute myelitic process attacking a more or less extensive region of the anterior cornua and the adjacent anterior and lateral columns [but he does not seem to be aware of the recent researches of Westphal and Bernhard on the implication of the large ganglion-cells.—*Rep.*] He then describes some cases of spinal infantile palsy which recovered entirely without leaving any bad effect, and which he calls 'temporary spinal infantile paralysis.' The name was first employed by Kennedy (*Dublin Journal of Medical Science*, 1860) who distinguished between 'temporary peripheral' and 'temporary central' cases. This temporary palsy resembles the ordinary form in the character of the paralysis, in the atrophy of single muscles or of groups of muscles, and in the retarded growth or deformity of one or more limbs; but it differs in the ultimate course. As a rule, it begins with feverishness, deafness, delirium and convulsions. In a short time, over night or in the course of a few days, the muscles become palsied to a maximum degree, sometimes in both extremities at once, sometimes in only one, oftenest in an arm; and they lose more or less completely their faradic excitability. When the voluntary power over the muscles has returned, the susceptibility to faradic and galvanic stimulation may be long absent. Rosenthal showed this last fact very clearly, and contradicted Duchenne, who said that the gravity of the prognosis was in direct proportion to the atrophy of the nerves giving rise to the lesion, which atrophy could only be found out by electrical investigation. Rosenthal affirms that in many cases, after six or nine months from the date of the affection, the electric excitability of the invaded muscles is *minus*, though voluntary movements are again present. In temporary palsy the limb does not, as a rule, become emaciated, whilst at times it does so remarkably; and yet both nerve-conduction and contractility return. Volkmann has seen instances of temporary palsy where the nerve-conduction was renewed to its full extent, but the growth of the limb was impeded.

The prognosis of complete cure is inversely as the duration of the paralysis. The duration of temporary paralysis is generally from one to two months; palsies which after a course of six to nine months do not seem to improve, must be regarded as lasting. The better the reaction to faradic currents remains, the better is the prognosis; but, on the other hand, loss of electrical excitability, at least in the first six or nine months, is not absolutely against a favourable issue; for the return of muscular contractility is not bound up with that of electrical. The smaller the extent of muscular atrophy, the more favourable is the prognosis; yet moderate atrophy does not preclude restitution of contractility and voluntary power.

One hypothesis of the pathological condition in this temporary disease is a dilatation of the small vessels with moderate collections of coloured blood-corpuscles in their interior, and perhaps of white corpuscles in the lymph-sheaths, swelling of the neuroglia from oedema, and increase in size of the stellate elements with copious proliferation of nuclei, swelling of the ganglion-cells and nerve-tubes (especially of the axis-cylinder), as seen in fresh cases of traumatic and spontaneous myelitis. These effused products, however, never soften or disintegrate; they are reabsorbed. Temporary spinal palsy is therefore a very acute polio-myelitis ending in resolution of the earliest

stages of inflammatory hyperæmia and serous swelling.

Duchenne de Boulogne, in his last edition, says that in adults spinal palsies occur which are absolutely identical with the 'atrophic paralysis of youth'; and that they occur from an identical lesion, viz., acute inflammatory atrophy of the cells of the anterior cornua; that it is met with in persons up to forty-five years [of age]; that it generally comes on from cold, and does not imply hereditary taint; the only exception to the analogy being that the osseous system does not in adults suffer so great atrophy as in children. It might be confounded with the paralysis occurring after diffused myelitis; but, in the latter, sensibility is affected, the bladder and rectum are paralysed, and sores form on the sacrum. Kussmaul agrees with him, and relates three cases supporting this view, the practical result of all being a favourable prognosis for similarly diseased persons, in opposition to Hasse's view that the complaint is dangerous to life. Brown-Séquard's experiments showed that, after severe temporary injury to the cord, entire restitution of function as regards influence of the will and electrical excitability could follow. Cold-water applications to the head seem to relieve the febrile symptoms in the first stages; but the later symptoms are most relieved by electricity and galvanism.

T. C. SHAW, M.D.

EBSTEIN AND MÜLLER ON THE TREATMENT OF GLYCOSURIA WITH CARBOLIC ACID.—The pathology of diabetes is confessedly so obscure, that there can scarcely be said to be any rational method of treatment. The authors of an interesting paper in the *Berliner Klinische Wochenschrift* for December 8, suggest that, in very many cases, abnormal processes of fermentation may be the cause of the glycosuria, or, at least, permit its occurrence. For example, there is a widely received opinion that one cause of glycosuria is increased sugar-formation in the liver, either by actual increase of sugar, or formation of sugar-forming ferments or zymotic materials. If then we can find a medicine which may check the formation or the action of these fermenting principles, our therapeutic efforts are likely to be successful in a certain class of cases. For this object their previous knowledge and experience of carbolic acid (the authors say), made them believe that this medicine would be useful in diabetes. Carbolic acid, or bodies of nearly similar constitution, had been used for this purpose, particularly creasote (Krupp's translation of Dr. Prout *On Diseases of the Stomach and Urinary Organs*, p. 143.) Dr. Prout, indeed, says that creasote diminishes the quantity of urine, but not the percentage of sugar. Griesinger (*Studien über Diabetes*, *Archiv für Physiologische Heilkunde*, 1859, p. 51) narrates a case of mellituria in a medical student, in which creasote had no effect, though his urine became free from sugar as soon as he became too busy to examine it. Latterly, creasote has scarcely been mentioned in the treatment of diabetes, and Jul. Vogel (*Virchow's Handbuch der speciellen Pathol. and Therapie*, vol. vi. part 2, p. 507) says that it does not help at all in the cure of the disease. But carbolic acid appeared to the authors to be far preferable to creasote, as being more definite in composition, less unpleasant in smell, and tolerated, as will be seen in the sequel, in far larger doses. The first case in which they used it was strikingly successful.

A dentist, aged forty-six, began the treatment on February 26th of last year. The diabetes was not hereditary. Two cousins had mental disease. He could not remember any special previous complaints. He had been seven years in the army, in actual service. The beginning of the diabetes dated from the preceding October. He ascribed it to family troubles, and pecuniary anxieties. Thirst and appetite were markedly increased, and the urine amounted to 8 litres ($1\frac{1}{2}$ gallons nearly) in twenty-four hours. His bodily weight had much decreased. From 204 lbs. he had fallen to 170 lbs. when weighed six weeks before, and he was lighter now than then. Sexual power was much diminished. The saliva was glutinous, but 3 grammes of perspiration collected on one occasion were free from sugar. His urine on February 26th had a specific gravity of 1.032, with 2.86 per cent. of sugar. He was ordered to take six or seven tablespoonfuls daily of a solution of carbolic acid (1 in 300). In three days he had used 1 gramme ($15\frac{1}{4}$ grains nearly). On March 4th the urine had a specific gravity of 1.013, and was free from sugar. The patient had taken half a drachm of carbolic acid. Thirst was less; the quantity of urine was not increased; he did not now get up at night to pass it. On March 4th, 5th, and the morning of the 6th the patient took no carbolic acid, and the urine, whose specific gravity ranged from 1.022 to 1.035, contained from 0.5 to 3.3 per cent. of sugar. He now resumed the carbolic acid, and on March 8th the specific gravity was 1.022, and the sugar only 0.2 per cent. He had no thirst; the appetite and quantity of urine were normal. After March 12th there was no more sugar to be found; the strongly acid urine always contained uric acid. On March 17th the urine passed in twenty-four hours was only $30\frac{1}{2}$ ounces. His bodily weight increased gradually. On April 27th he weighed 173 lbs., and on May 26th, 185 lbs., and appeared perfectly well. He left off the carbolic acid on March 31st. In July there was a slight relapse; but three days of the carbolic-acid treatment set him all right again. It should be stated that his gums were spongy, and bled on both occasions. This patient was on a mixed diet all the while.

The authors do not propound this as an universal remedy; indeed, they give a case of a merchant, aged twenty-three, whose urine had a specific gravity of 1.035, with 4.85 per cent. of sugar on August 2nd. The urine passed at night next day had a specific gravity of 1.045, and contained 6.1 per cent. of sugar. He took 3 grammes of carbolic acid without any benefit.

The authors give a third case, in a merchant, aged fifty-four, who had suffered eleven years from glycosuria. The disease was not hereditary, but commenced with severe mental distress. One sister died with mental disease. The percentage of sugar varied of late years from 2.5 to 5 per cent. In 1868 he had an apoplectiform attack, and his speech became indistinct. Then ensued a paralysis of his muscles of deglutition, so that he was obliged to be fed with a tube for ten weeks; and simultaneously he had considerable alterations of sensation in the right face and left half of the body. Motility remained intact. He partially recovered, but with some disturbance of sensation in the regions described; for example, cold objects felt hot to his left hand, while his right hand felt a peculiar numbness, which bothered him in shaving. He had been

eight times at Carlsbad, always with temporary benefit of a striking nature, but he always relapsed when away from that place. The quantity of urine was now $4\frac{1}{2}$ to $5\frac{1}{2}$ pints in twenty-four hours. The specific gravity was 1.043, and the sugar 5 per cent. On April 8th there was a sediment of uric acid. In twenty-one days he took 7 grammes (108 grains nearly) of carbolic acid. During this time the sugar varied from 3.1 to 4.3 per cent. On leaving off the medicine, the quantity rose from 4.5 to 4.8 per cent. He then went to Carlsbad. On arriving there, the sugar was 5.75 per cent. After six weeks there, it was only 1.43 per cent. On leaving Carlsbad he resumed the carbolic acid, and took $7\frac{1}{2}$ grains daily. With this and a flesh diet, the sugar was kept down, and on September 2nd there was no sugar in the urine. On his leaving off the carbolic acid, the sugar again returned; whereas, while taking it, he not only suffered no inconvenience, but kept the sugar down to a few tenths per cent. The authors' formula is as follows. A gramme of crystallised carbolic acid is dissolved in 250 grammes of distilled water, and 50 grammes of peppermint water. This is all taken in three days, so that the patient takes six or seven tablespoonfuls daily.

The following formula will be nearly identical:—

| | |
|----------------------------------|------------|
| Crystallised carbolic acid . . . | 16 grains. |
| Peppermint water . . . | 2 ounces. |
| Pure water to . . . | 10 ounces. |

A tablespoonful to be taken six or seven times daily.

In this last case the daily dose of crystallised carbolic acid was $7\frac{1}{2}$ grains.

In a postscript the authors state that the dentist mentioned above came again on October 29th, after a fortnight's return of his old symptoms. He was completely impotent; but otherwise better. His weight was 195 lbs. His urine had a specific gravity of 1.030, and contained 2.25 per cent. of sugar. After the use of one gramme ($15\frac{1}{4}$ grains) of carbolic acid, in the manner above described, the sugar again vanished completely from the urine.

[This paper of Drs. W. Ebstein and Julius Müller is both pleasantly and modestly written. I have, for the sake of condensation, omitted several deprecatory expressions, which show the caution with which the writers propound their views.—*Rep.*]

FRIEDREICH ON CANCER [?] CURED BY CONDURANGO.—The *Berliner Klinische Wochenschrift* for Jan. 5, 1874 (no. 1) has an article by Professor N. Friedreich, of Heidelberg, recommending the use of condurango, and giving the following case in illustration. Jacob S., aged fifty-four, a day-labourer, became a patient of the hospital on January 10, 1872. For ten months he had complained of loss of appetite and 'weight' at the pit of the stomach, especially after meals. This afterwards increased to absolute pain, which radiated towards the left shoulder. Of late he had had stabbing-pains in the left half of the epigastrium. Vegetable diet increased his pain, and often induced vomiting of a clear, watery, acid fluid. No blood was vomited. His strength and nutrition declined daily. He was very cachectic and anæmic; his naso-labial lines were very strongly marked. He was much emaciated, and extremely weak. The skin was dry and harsh. There was increased resistance in the epigastric region, which was somewhat distended. Between the xiphoid process and the umbilicus, especially towards the left, and overlapping the left border of

the rectus muscle, it was easy to make out hard nodular tumours connected with each other, very sensitive to slight pressure; and in deep breathing a kind of creaking peritoneal rub could be clearly felt. The tumour was dull on percussion. The left lobe of the liver was enlarged to three fingers' breadth below the margin of the ribs; its surface was smooth, and not tender or painful. The left lobe was continuous with, or at least undistinguishable from the tumour noted above. The left supraclavicular fossa was filled with a mass (*paquet*) of swollen, hard, but painless lymphatic glands about the size of hazel-nuts. The spleen, lungs, and heart were normal, but the action of the latter was very feeble. The bowels were confined. The tongue was slightly coated. He had occasional nausea. The urine was pale yellow, slightly turbid, of specific gravity 1.014, and free from albumen. Once now and then in the evening, there was slight and transitory elevation of temperature ($38^{\circ}\text{C.} = 100.4^{\circ}\text{F.}$), otherwise it was normal, sometimes subnormal (to $36.2^{\circ}\text{C.} = 97.1^{\circ}\text{F.}$). The diagnosis arrived at was cancer of the stomach, implicating the epigastric and supraclavicular lymphatic glands. Bicarbonate of soda with muriate of morphia was ordered (in form of a powder) thrice daily. Fluid nourishing diet was given. On Jan. 23 he left the hospital, without much change, except alleviation of the epigastric pain, and loss of the peritoneal friction-sound. On the 31st he came back, having again been attacked with new and more severe pains. There was also more fever (temperature in the morning $38.4^{\circ}\text{C.} = 101.1^{\circ}\text{F.}$; evening, 39.2° to $39.6^{\circ}\text{C.} = 102.5^{\circ}\text{F.}$ and 103.3°F.), but after a few days, when the pain decreased and a peritoneal friction-sound again appeared, the temperature again became normal. Occasionally the epigastric pains would become more severe for a day or two, and febrile symptoms set in. The lower part of both legs on readmission was somewhat cedematous, but this disappeared with rest in bed. There were occasional sediments of uric acid in his urine. On Feb. 18, he was ordered the following mixture: *R* Condurango bark four drachms; macerate for twelve hours with twelve ounces of distilled water; then boil down to six ounces, and strain; one tablespoonful to be taken twice a day.

This medicine was regularly taken and well-borne. His diet was carefully regulated and entirely liquid (milk, broth, raw eggs). As early as March 2, the epigastric tumours appeared smaller, and the pain in that region, as well as the tenderness on pressure had diminished. On March 10, it was evident that the supraclavicular glands were decreasing; and from day to day this went on. On March 17, the epigastric tumours were indubitably smaller, and less nodulated. From March 22 he took one-and-a-half tablespoonfuls of the condurango mixture three times a day. During March he gained strength, and improved in every way. His appetite improved; his pains and dyspepsia vanished; the bowels acted spontaneously; and at the end of that month there was no increased resistance in the region of the stomach; only, left of the median line, and near to but below the xiphoid process, there was still a small hard uneven tumour to be made out with some difficulty, and from day to day this diminished. The rest of the abdomen was soft and free from pain. In the middle of April the epigastric tumour had left a residuum of the size of a hazel-nut. The patient was better in every respect, and took daily walks. During May he left the hospital for a few days, and on

June 15 he was discharged—perfectly well, except that on deep palpation, the little hard round, hazel-nut like painless tumour was still to be felt to the left of the xiphoid process. Since then, repeated examinations have convinced Dr. Friedreich of the permanence of the cure.

He remarks that there can be scarcely any doubt of the diagnosis; the long combination of the symptoms, the extreme emaciation, and the fact of the tumours being plainly felt, the peritoneal friction-sound the enlargement of the supraclavicular glands, all seem to him to point to cancer. The absence of symptoms of stenosis of the pylorus pointed to a part of the stomach remote from this as the seat of the disease. Believing this he thought it right to try condurango bark, which is a popular remedy amongst the inhabitants of Ecuador (South America) for cancerous and other chronic diseases, and attracted such attention that a commission was sent to Ecuador by the United States' Government in 1871, and an independent medical committee investigated its action in New York (Drs. Buck, Markoe, and Draper); at the Middlesex Hospital Messrs. Hulke & Morgan tried it, as well as another Englishman, Dr. Pearce. In Italy Drs. De Sanctis and Palmesi also made trials of it. Though none of them confirmed the original accounts of its success, they all seemed to think it had some soothing and other beneficial effects.

In a footnote Dr. Friedreich adds an account of condurango (*Equatoria Garcinia*, or *Gonolobus Cundurango*), which states *inter alia*, that the bark produces in animals energetic topical effects (convulsions, and increased reflex irritability, or even death). The subcutaneous application of the decoction induced apathy, torpor, and afterwards tetanic convulsions in frogs. Shortly before death nervous irritability was destroyed, but that of the muscles remained intact. In other frogs, death occurred without spasms. The heart stood still, but could still be stimulated to contract. No signs of irritability could be detected in the parts to which it was applied. The decoction is said to succeed when the infusion fails.

Vulpus gives an analysis stating that the bark contains tannin, sugar, albumen, starch, malic, oxalic and tartaric acids, as well as two peculiar resins, and a bitter crystallisable material which appeared the only active medicinal principle. Dr. Friedreich has tried the same remedy in a few other cases, with less success, which he ascribes to the impatience of the patients, who discharged themselves from his wards.

[The reporter has no prejudices either for or against condurango. He perfectly agrees with Professor Friedreich that there is no *à priori* argument against the existence of a drug which should be as specific against cancers as iodine is for bronchocele, or mercury for syphilitic gummata and the like, and which might induce retrograde metamorphosis of the cellular elements of malignant tumours. He agrees further with the professor that condurango deserves further trials. But he cannot admit that this was an undoubted case of cancer of the stomach. The very clear, candid, and faithful report of the case supplies to the mind of the reporter very grave reasons for doubt. It does not appear that there was any special reason for considering the tumours cancerous, except the character of the pain and the amount of the cachexia. The reporter has seen cases closely resembling the one recorded, which were undoubtedly syphilitic, and not cancerous; and he has been informed by emi-

nent surgeons that many such tumours, masses of glands, and the like, have been removed by the knife, or otherwise, under the erroneous impression that they were cancerous. The one-sidedness of all the 'tumours' is a common feature of tertiary syphilitic lesions; and the febrile exacerbations, though slighter than they often are, agree very well with this view of the case.—*Rep.*

W. BATHURST WOODMAN, M.D.

SURGERY.

BRYANT ON POPLITEAL ANEURISM TREATED BY THE INTRODUCTION OF HORSE-HAIR INTO THE SAC.—Mr. Bryant (*Guy's Hospital Gazette*, Dec. 6) has quickly followed the practice of Levis, in a case treated at Guy's Hospital on Nov. 25. The aneurism was of some standing, its presence having been recognised six or seven months previously by the patient, who was an unfortunate subject for the ordinary modes of treatment, since he suffered from mitral disease of the heart, and undoubtedly had very bad arteries; and, although no other aneurism had been discovered by a careful search, still one might exist unknown, for instance in the thoracic cavity. Pressure had already been tried for a fortnight or three weeks off and on; but the only effect of this had been to harden the aneurism, showing that some coagulation had taken place on the walls of the sac, but not sufficient to cure it. He was unable to bear any further pressure. During the pressure he suffered from epistaxis, but this was not due to the aneurism, but rather to the mitral regurgitation. However, it pulled him down a good deal, so the treatment by ergot was tried, as recommended by Langenbeck; but, though it improved the pulse, and stopped the epistaxis, the aneurism was evidently increasing in size; indeed, during the last three days it had become half as large again as it was when the man was admitted. Mr. Bryant introduced a very fine trochar and cannula, and, withdrawing the former, he passed through the cannula about eighteen feet of horse-hair. This was accomplished in a few minutes, three threads of hair being pushed in together. Blood flowed through the cannula, though the artery was compressed, till the end of the operation, when it ceased; and, when the cannula was withdrawn, there was no bleeding from the wound, which was closed with some of Mr. Bryant's mackintosh strapping. The leg was covered with cotton-wool, and the patient was removed to the ward, the aneurism still pulsating, but not so strongly. The patient has since died.

BILLROTH ON GRANULATING FLAPS IN PLASTIC OPERATIONS.—*The Berliner Klinische Wochenschrift* for November 3, contains a short abstract of a paper by Billroth on a method of obtaining as long granulating flaps as possible in plastic operations. Dr. Billroth, from large experience in operations for epispadias and for extroversion of the bladder, considers that it is sometimes desirable to obtain very long flaps for the covering in of the bladder. As the base of these flaps, in the localities concerned, often could not be extended beyond a limited breadth, and since the thin tegumental tissues readily become gangrenous, he first of all marked out and cut the edges of the flaps, and dissecting them off, left them attached to the body by narrow bridges. He next

laid lead-foil beneath the tissue thus separated, and gently constricted one end of the flap by a ligature. Separation followed, and the under surface of the flap granulated in about six or eight days. In order that such granulating flaps may become fixed in their new position, it is necessary to freshen their edges superficially. Dr. Billroth has, by this method, obtained flaps an inch and a-quarter broad by four inches long, under circumstances in which a freshly formed skin-flap from the abdominal wall would undoubtedly have become gangrenous. He has applied this method in other parts of the body with equal success.

PLAGGE ON TRAUMATIC ANEURISM OF THE FEMORAL ARTERY, TREATED BY INJECTION OF ERGOTIN.—In *Betz's Memorabilien*, vol. xviii., part 10, Dr. Plagge of Darmstadt records the following case. A man was accidentally stabbed with a small bread-knife about two finger's breadth just beneath Poupart's ligament, and the result was a traumatic aneurism. An icebag was applied, and digitalis and morphia administered internally. The tumour however increased, and two days afterwards, a solution containing $2\frac{1}{2}$ parts of extract of ergot and $7\frac{1}{2}$ each of spirit of wine and glycerine was subcutaneously injected on the inner side of the tumour, and the ice-bag assiduously applied. In the evening of the same day the swelling had become harder and more limited. On the next day the aneurismal thrill had lessened. For the next three weeks these injections were continued. At the end of this period, there was visible diminution of the impulse, swelling and sensibility to pressure; and the patient could bear slight pressure for an hour at a time thrice daily, and the ergot injection was discontinued. A fortnight later, the impulse was scarcely perceptible, the tumour hardly was larger than a hen's egg and not very sensitive. Roser's tourniquet was applied, and the man was sent home. A month later, he presented himself with the aneurism cured.

Dr. Plagge concludes from this case that the subcutaneous injection of ergot materially assists in the lessening of large aneurisms, the radical cure of which would only be effected by ligature or compression. In this case, ligature (of the external iliac) would probably have terminated fatally. The plan of treatment by ergotin was recommended by Langenbeck.

BÖTTGER ON THE CONSERVATIVE SURGERY OF THE SHOULDER-JOINT.—Dr. Böttger of Dessau reports at some length the following case, as a contribution to conservative surgery (*Betz's Memorabilien*, vol. xviii. part 10). The patient was wounded at Metz, on August 18, 1870, by a bullet which passed through the shoulder-joint, and disarticulation was proposed at Ars, but abandoned on account of his feeble condition. On August 26 he came under Dr. Böttger's care, at Dessau, with a profuse discharge of fetid pus from a sloughing-looking wound with everted edges, on the anterior aspect of the axilla. There were great swelling and pain in the shoulder-joint, and in the whole upper arm. The bullet had penetrated close to the lesser tuberosity of the humerus, and had passed obliquely inwards and upwards through the joint, smashing the head of the bone just beneath its articular surface, and emerging behind. On passing the finger into the wound, three or four fragments of bone could be felt, with much loss of substance. The patient was much reduced, and, from symptoms of pain in other parts, there was a fear of pyæmia. Dr.

Böttger, therefore, did not consider operative interference, either by resection or disarticulation, admissible, and therefore determined on attempting conservatism; 1. to raise his prostrate strength; 2. to subdue the local inflammatory action; and 3. to prevent the absorption of the fragments. The wound was carefully syringed with warm chamomile and carbollised lotions, and simply bound up with charpie; and for the present the laying bare of the cavity (the source of the copious flow of pus) was omitted on account of the possibility of hæmorrhage and of the prostration of the patient. Wet compresses were applied, and fastened with a bandage; phosphoric acid, raspberyyade, and *bouillon* were ordered; and the following day bicarbonate of potash and *nux vomica*. The case went on well, the patient improving by degrees, and taking food well; and by September 9 the track of the wound began to get clean, but yet discharged a little pus. A small piece of compressed sponge was introduced into the wound, with the idea that, once soaked with the existing secretion from the wound, it would prevent the retention of the discharge; that, by the removal of the stagnant pus, the production of granulations would be favoured; and that it would prevent early closure of the canal. In a fortnight's time slight passive motion was commenced. The process of exfoliation of the bone, and of the healing by granulation of the track of the wound, was observed by means of Kramer's ear-speculum, which could be easily introduced without any pain. By November 25 the region of the shoulder had become rounder and more natural in shape; and, notwithstanding that the elevator muscles of the arm had been deprived of their insertion, it could be raised to nearly a right angle, and lateral motion was very free.

Dr. Böttger contrasts this case with one in which a similar wound had been inflicted, and where resection of the head of the humerus by Nélaton's method had been performed, with a result by no means satisfactory, as there was great shortening of the limb, with the retention of very little power over it.

[The case reported by Dr. Böttger is, in some respects, similar to one observed by the reporter in civil practice, where a revolver bullet, entering the axilla obliquely, had completely smashed the head and neck of the humerus. The ball, which had just missed the axillary artery, was extracted and the fragments of bone adjusted, the limb carefully supported by splints, and the wound kept very clean; the patient recovered with nearly perfect movement of the arm. Of course the case reported is the more remarkable from its accessories, and from the want of immediate attention.—*Ref.*]

EDWARD BELLAMY.

BARDINET ON A NOVEL METHOD OF REDUCING PARAPHIMOSIS.—M. Bardinet of Limoges (*L'Union Médicale*) describes the case of a young man who converted the congenital phimosis, of which he was the subject, into a paraphimosis. This was followed by swelling and pain. At the expiration of twenty-four hours, M. Bardinet was consulted, after one of his *confrères* had failed in an attempt at reduction. This surgeon found the preputial ring tightly constricting the corpora cavernosa, and the glans penis very swollen and of a deep red colour. He tried the ordinary methods of reduction for some time, but failed. Then the idea struck him of acting on the pre-

putial ring by its deep aspect as well as by its external surface. It occurred to him that, if he could introduce a lever between the tight ring and the corona glandis, he might raise the ring and depress the corona, the prominence of which formed the obstacle to be surmounted. In the absence of any surgical instrument, he made use of two hair-pins. These presented two levers, which were at the same time blunt, light, but sufficiently strong, and of a size in proportion to the separation of their branches. By bending down the glans and drawing the preputial ring towards the pubes, he found that he could easily glide the blunt rounded end of one of the hair-pins between the preputial ring and the body of the penis. It not only entered without trouble, but could be pushed on to a sufficient depth. Encouraged by this, he inserted, as soon as possible, the second pin in the same manner. The two pins being well fixed, he began a seesaw movement, with the three-fold advantage of lowering the prominence formed by the corona, of raising the preputial ring, and of establishing before it an inclined plane, on which it might smoothly slide. He next practised the ordinary method of reduction, and, after a few efforts, succeeded completely.

He thinks that in the majority of cases it would be as easy to insert the lever as it was in his case. He believes that adhesions which might oppose the use of the lever are less frequent than they are represented to be. He draws attention to the fact that the whole prepuce does not become the cause of the strangulation, but the constriction is by the preputial ring, which corresponds to the union between the mucous membrane and the skin. That ring, very strong and resisting, in some cases acts like a cord. Behind the ring, the prepuce is supple. The author suggests several other things which might be employed instead of the hair-pins, viz., a spatula, the handle of a small spoon, or any blade with blunt edges. One need not limit oneself to the lever action only; a dressing forceps (*pince à anneaux*) combines a dilating power with the lever; the forceps with three branches, made for dilating the wound in tracheotomy, might be still better. Blunt round flat hooks, elevators of the eyelids, might be employed. In introducing blunt hooks, they should be applied on the back of the penis; the beak should be slid under the constricting ring from before backwards; they should then be made to describe a half-circle forwards, and by that movement the preputial ring would be firmly caught. With two hooks a triple result might be accomplished: dilatation of the ring, traction from behind forwards, and depression of the corona, over which the prepuce is to be brought.

[The simple plan resorted to by M. Bardinet seems admirably adapted to the nature of the case, and is a valuable addition to the old plan of reduction. However, it is obvious that it can only be applied in a limited number of cases, viz., those which are seen by the surgeon within the first two or three days after the accident.—*Ref.*]

JOHN CROFT.

SYPHILOGRAPHY.

ALBUTT ON THE OBSCURER NEUROSES OF SYPHILIS.—Dr. Clifford Allbutt contributes to the third volume of the *West Riding Lunatic Asylum Medical Reports*, an interesting paper on the Obscure Neuroses of Syphilis. Under this head he includes those disorders which are generally con-

sidered functional, 'those which depend, so far as we can tell, upon tissue changes which are not obvious, or to be discovered by the microscope.' The following is a rough classification of them.

1. 'Intellectual and emotional disorders, such as dementia, depression, fever, melancholia, delusion, morbid susceptibility, irritability of temper, "loss of tone," and so forth.
2. 'Sleeplessness.
3. 'Motor defects, such as tremor and muscular debility, perhaps epilepsy.
4. 'Neuralgia, occurring in both superficial and visceral nerves.
5. 'Intestine defects, such as anæmia, &c.'

Dr. Allbutt says that these phenomena 'are often fugitive or unsettled in position, and when cured, if they relapse, it is often under new forms.' The prognosis in these cases is much more favourable than in optic neuritis, or in neuritis of the third, sixth, or other cranial nerves. 'With a little care and patience we may almost promise the patient that he shall be cured, and the cure is generally as permanent as it is easy. A course of mercury, gently prolonged, a month at Aix, or large doses of sarsaparilla, will rarely fail to dismiss the evil for once and all, so far, at least, as that particular manifestation is concerned.'

Dr. Allbutt cites some cases illustrative of his remarks. J. B. BRADBURY, M.D. (Cambridge).

PONCET ON SYPHILITIC MENINGITIS.—M. Poncet (*Annales de Dermatologie et de Syphiligraphie*, 4me année, no. 3) related the following case.—The patient believed to have this affection was a prostitute, twenty-six years old, admitted into the Lyons Hotel-Dieu on Feb. 7, 1872. She contracted syphilis a year before, and thenceforth had at long intervals relapses of that disease. Headache at night, without obvious cause, was frequent. Shortly before admission this headache increased violently, and was followed by shivering and by obstinate vomiting. Speech was slow, difficult: the eyes were half closed, the pupils dilated; pain was referred to the forehead and nape, where the muscles were strongly contracted, drawing the head backwards. The abdomen was soft, and retracted. Vomiting continued, though less frequent. Pulse 92, and temperature in the rectum 98.6° F. There was general hyperæsthesia, accompanied by momentary contraction of the muscles. She was ordered to have ice applied to the head and calomel given by the mouth. The low temperature and even pulse continuing, the possibility of syphilis was suggested, and inunction was practised, while iodide of potassium was given internally. In one day the temperature fell to 97.7° F., and the pain greatly diminished. The next day the pain and vomiting were altogether gone, and the patient slept naturally. As experiment the mercury and iodide were withheld, and the temperature immediately rose to 99° F. The pain returned to the nucha and forehead the next day, and nausea was troublesome. Sixty grains of iodide of potassium were then given in the twenty-four hours. The pain left her, she could sit up and talk, and asked for food. The temperature was 98.75° F. to 99.2° F. The next day, the iodide was not added to her daily medicines. The frontal pain and nausea returned, with wakefulness; pulse 78, temperature 99.2° F. The iodide was withheld three days, during which time the slowness of speech, wandering looks, general hyperæsthesia, and vomiting returned. The

temperature fell to normal in the morning, but rose to 99.2° F. at night. After this the iodide was steadily administered, 60 grains per diem, and in seven days the patient left the hospital, quite free from her symptoms. Three weeks later she retained the same absence of cerebral irritation, and was apparently in good health.

The leading peculiarities of this case were, invasion by headache, shivers, and vomiting; the persistency of the headache and vomiting; the stiffness of the neck and the behaviour of the patient. These pointed to a meningeal irritation. The low temperature and regular moderate pulse, on the other hand, were very unlike those met with in ordinary meningitis, and induced the suspicion that the meningeal irritation was due to syphilis, which the complete control possessed by iodide over the symptoms greatly strengthened.

[A case very similar to this was reported by Duval (*Archiv für Dermatologie und Syphilis*, vol. iii. 1870.) The patient was infected in 1864, and had the usual series of syphilitic affections. In 1867, he had paralysis of the left motor oculi. In 1868 he vomited twice daily for a considerable period, and had constant headache. Ordinary treatment was of no effect; but a complete cure ensued on the administration of iodides of mercury and potassium.—*Rep.*]

MILDNER ON INTRACRANIAL SYPHILIS CONNECTED WITH INTELLECTUAL DISTURBANCE.—Dr. Mildner (*Wiener Medizinische Wochenschrift*, July, August, 1872) was for fifteen years chief resident physician in the Vienna Asylum for Lunatics from rural districts, viz., from 1854 to 1869. In this period 5,529 lunatics were admitted. In recording their cases, special reference was made to the history of the patients' past sexual life, and to the condition of the genitals, and particular research was made for symptoms of syphilis or its consequence. But the author was able to trace syphilis as the chief cause of the intellectual disturbance, either during life or after death, in fifteen cases only. In five of these cases the skull-cap was thickened at its inner table, the outer one worm-eaten, in different situations. The brain-tissue was softened, the right centrum ovale being in one case converted into a glossy yellow substance.

[The class from which the patients were derived is that most free from syphilitic contagion, dwellers in rural districts; hence this very small proportion of syphilitic disease must not be taken as the usual one among the insane.—*Rep.*]

EISENSCHITZ ON THE LATENT STAGE OF INHERITED SYPHILIS.—Dr. Eisenschitz (*Wiener Medizinische Wochenschrift*, nos. 48 and 49, 1873), confines his remarks to that interval after birth which in many infants precedes the external characteristic manifestations of the disease, and to which the most trustworthy observers accord a duration of six to twelve weeks. He describes the symptoms that are usually present even in this apparently latent period, which, taken together, enable the physician to suspect the existence of syphilis, and justify him in instituting specific treatment without waiting for generally recognised signs. He remarks that in families infected with syphilis, the earlier children usually manifest their disease at birth or very soon afterwards; but it is among the later children this interval of latency is most commonly observed,—in those generated when the syphilitic influence in the parents is waning. The author compares the latent

stage to the interval that is met with between the disappearance of one syphilitic rash and the development of another. In discussing the importance of ascertaining the previous medical history of the parents, the author states that he believes that the child always inherits the disease from the mother, never from the father, while the mother remains unaffected: a doctrine of practical importance, as it neutralises any scruple against urging the mother to suckle the child herself, and one of the great difficulties in treating inherited syphilis is thus avoided—that of finding an artificial food which the feeble digestion of a syphilitic child can assimilate.

No wet-nurse should be employed unless she be made fully aware of the possibility of her contracting syphilis herself from the child. On this point, he mentions that Günzburg (*Österreichische Jahrbücher für Pädiatrik*, vol. ii. 1872) has recently published an opinion founded on a considerable number of observations at the Moscow Foundling Hospital, that wet-nurses are not contaminated by infants who have inherited disease, and that, when women are infected by children they suckle, the children have acquired, not inherited, their disorder. Eisenschitz, however, declines to agree with Günzburg on this point, and falls back on the known immunity of mothers when suckling their offspring.

The majority of children with inherited disease are feeble and ill-nourished. When this state is very marked, and the child dies from 'debility,' the viscera usually contain characteristic conditions of a syphilitic kind. A close examination of children wasting from syphilis, usually detects about the corners of the mouth or anus the beginnings of the fissures and mucous patches, that shortly make the presence of syphilis obvious. When the child, however, seems well-nourished at birth and has the usual weight or is even heavier than the average, and continues to grow, it is most important to detect the existence of syphilis, for in him it is curable and he may recover completely.

Such infants nevertheless are usually very anæmic, though their complexion is not of bloodless pallor, but like alabaster with a yellowish tinge. They do not behave like healthy children who, when lying in the nurse's lap, laugh and throw about their limbs when noticed; they lie still, or are fretful with their own discomfort. Indigestion of some kind is usually present, even when the child is regularly suckled by his mother or by a healthy nurse. The child cries much, is restless and wakeful at night. This restlessness is partly due to the direct influence of the syphilitic poison, but in a greater degree to coryza. The coryza may be very slight, and may exist a long time before the attendants are aware of it, or before it becomes abundant, purulent, or bloody. Yet the secretion is sufficient to plug the deeper parts of the nasal passages and thereby hinder respiration. The child then lets go the nipple constantly when sucking to get breath, sleeps with his mouth half open, and so makes his mouth and throat dry. Even when awake the child's mouth is constantly open, and thus his face has a peculiar expression. The spleen is enlarged almost invariably very early, long before the eruption appears. To detect this, the hand should be laid on the belly at the middle line, and gently passed outwards to feel the big spleen lying beneath the ribs. Eisenschitz says, in children thus suffering, whose parents have had syphilis, it is right to begin mercurial treatment at once, as by that means the

further development of the disease may be arrested. If syphilis be the cause of indigestion and restlessness, these speedily diminish, and the child improves in weight. It is often requisite to conceal the nature of the child's disease from its attendants; for this he prefers calomel, given by the mouth, as that remedy is employed for a variety of ailments unconnected with syphilis, and inunctions with mercurial ointment coloured with some pigment; the inunctions being ordered ostensibly to relieve colic or flatulence.

The nostrils should be cleared and brushed with red precipitate ointment, and the child's nose now and then tickled till he sneezes, so as to blow out the mucus before it dries into crust.

MOUSTAPHA FAID ON PERVERTED NERVOUS SENSIBILITY IN SYPHILIS.—This physician has published an essay on twenty cases of this kind, reviewed in *Annales de la Dermatologie et de la Syphiligraphie*, no. 3, 1872-3, which contains the result of the investigations he carried out while Fournier's hospital assistant. He divides the cutaneous sensibility into three kinds, 1st, of pain; 2nd, of touch; and 3rd, of heat. During the early stages of syphilis these senses may be separately or conjointly affected, being sometimes increased, diminished, or perverted. Hyperæsthesia of the skin is very rare in syphilis; when present, it usually has near it anæsthesia or analgesia (loss of sensibility to pain). The hyperæsthesia occasionally attacks the mucous membrane, the muscular masses or the fibrous coverings of the joints. Perverted sensibility shows itself by sensation of cold being complained of in parts of the body where the temperature is normal, or even heightened by general febrile disturbance. Diminished sensibility may also be general to the three varieties of sense or limited to one. Most often analgesia is present, while sensibility to touch and heat are preserved. The sensibility to heat is the least often diminished. When analgesia is present, it affects a much larger surface than paralysis of the other senses.

These affections of the general sensibility are most frequently observed in females, and are accompanied by intellectual or other nervous disturbances that closely [and suspiciously—*Rep.*] resemble ordinary hysteria, BERKELEY HILL.

PIROCCHI AND PORLEZZA ON MYDRIASIS CONSEQUENT ON SYPHILIS.—The authors relate (*Giornale Italiano delle Malattie Veneree e della Pelle*, iii. 1872, and *Archiv für Dermatologie und Syphilis*, 1872) the case of a patient who was infected twelve years before the report; thenceforth he had wandering rheumatic pain without constitutional symptoms. In February, 1872, the patient, then forty years old, had a fixed pain in the right supraorbital region; mydriasis and loss of visual strength followed. General treatment was instituted first with iodide of potassium, then with the green iodide of mercury, and Calabar bean as a local application. On April 12th his state was as follows. The right papilla was much enlarged; iris sluggish; he had diplopia. Visual power was restored by looking through a hole in a diaphragm of card. The eye was otherwise normal. There was no skin-syphilide. He had slight swellings of the nuchal glands. By continuing the iodides of potassium and mercury, a complete cure in one month was obtained. On July 18th a similar condition of the left eye developed, and, being similarly treated, was also removed.

The authors attribute the affection to a gummy deposit in the sheath of the optic nerve, and to consequent disturbance of the sympathetic plexus surrounding it.

DERMATOLOGY.

BESNIER ON MILIARIA.—Dr. Besnier, of the Hôpital Saint-Louis, in an article on this affection (*Ann. de Dermatologie et de Syphiligraphie*, vol. v. no. 1), briefly describes the first outbreak of miliary fever at Leipzig in 1862, the important position it occupied in medical literature for a hundred years, and its gradual disappearance from nosology as a substantive disease, since the writings of De Haen (1760) and Gastilier (1778), until it is only to be found on patients' bed-cards in Italian hospitals. M. Gintrac, of Bordeaux (1859), Bazin (1862), Guéniot (1862), argue in favour of the occasional occurrence of a specific fever, accompanied with miliaria; but the few cases collected by the first-named author are too indefinite to found his conclusion on; Bazin's account is that of a vesicular eruption like roseola or erythema, without pyrexia or any grave symptoms; and Guéniot's observations refer to the scarlet fever of puerperal women.

Dr. Besnier next gives a careful account of the anatomy of a miliary eruption, but adds nothing of importance to the previous descriptions of Biesiadcki and Neumann. He justly remarks that, though the liquid of the vesicles is usually acid at first, and alkaline later on, this rule is liable to many exceptions; in fact, he discards any real difference between sudamina and miliaria. The favourite localities of the eruption he describes as the face, especially the forehead at the roots of the hair, the flexor surface of the arms, the back especially in rheumatism, the chest and groins in scarlet fever, and the abdomen in puerperal cases.

He distinguishes two kinds of miliaria:

1. An eruption of sudamina, attended with local redness, itching, &c., but without any fever. This is only seen in very hot weather, and is most common in the tropics. It appears to be closely allied to, if not identical with, the form of erythema well known as 'prickly heat' in India (*Lichen tropicus* of Bontius and Willan), and as *bourbouilles* in the Antilles.

2. A strictly secondary eruption of sudamina which may occur in the course of various diseases. Of these Dr. Besnier enumerates (1) the curious sweating-sickness, still endemic in some parts of the north of France, though happily it can no longer, as in the fifteenth century, be called *sudor Anglicus*; here sudamina are only occasionally present and of no special importance; (2) scarlet fever, where it is of some diagnostic value, when it occurs early on the chest and in front of the armpits; (3) small-pox, less common; (4) measles, rare; (5) phthisis and pneumonia; (6) rheumatism; (7) typhus; (8) intermittent fevers, rare; (9) puerperal fever, where the eruption may be accidental, as in other pyrexia, but sometimes accompanies the most fatal pyæmic forms of the disease.

In all of these cases the eruption is only symptomatic, so that the author agrees with Hebra in denying the existence of any disease which can be properly described as miliary fever.

SCHEDI ON CONGENITAL ALOPECIA.—Schedi publishes in Langenbeck's *Archiv* (vol. xiv.) two cases of congenital alopecia. In a piece of skin

excised from the scalp, the sebaceous and sudoriparous glands were found normal, and there were also follicles which resembled those of the hair and were provided with arrectores muscles, but showed no trace of a bulb. P. H. PYE-SMITH, M.D.

NEW INVENTIONS.

APOLLINARIS WATER.

The Apollinaris water belongs to the class of effervescent alkaline waters. It is not incorrectly described as a 'natural effervescent mineral water of great purity, very agreeable flavour, and valuable dietetic qualities.' The analysis of Bischoff, of Bonn, shows it to be a water intermediate in composition between the famous waters of Selters-brunnen and Kränchen at Ems. But it has advantages over both of these.

Apollinaris Water is certainly the queen of table-waters. It is softer and more refreshing than its only rival, Seltzer water (Nassau: Selters Brunnen), and is more pleasant to the palate. Over all manufactured aerated waters it has an incomparable superiority. The coarse chemistry of the laboratory can never rival the refined operations of nature, and in nothing is this more apparent than in comparing the attempts which are made even by the best manufacturers to imitate natural effervescent waters. The Apollinaris water is one of peculiarly happy constitution, and, skilfully bottled as it is under pressure at the Brunnen, it has all the sparkling qualities which alone make artificial waters tolerable—for what is more intolerable than the vapid flavour of artificial aerated water if the injected gas which disguises its crudity be allowed to pass off?—with the amenity and purity of a water in which antacid qualities are cunningly infused by the master hand of nature.

It is, moreover, a water of great organic purity—another highly important desideratum in which artificial aerated waters often dangerously fail. Its place seems, therefore, marked as the favoured beverage of the favoured classes, who can select their drinking-water. Its outlandish name is perhaps a little against it at first, but no doubt, after a little time, 'a bottle of Apollinaris,' and 'Apollinaris and Hock,' 'Apollinaris Cup' will be as familiar as 'S. and B.' Already, we believe, it is beginning to be known in some of the clubs by the affectionate diminutive 'Polly.' Physicians will find it a valuable addition to their resources, as a cool and refreshing drink, antacid, and useful in promoting digestion and removing gastric irritation. Such a water is the sworn enemy of gout, rheumatism, and their congeners.

MISCELLANY.

A MEDICAL VIEW OF THE POLITICAL POSITION.—Towards the result of the late election, a great number of causes conspired. One of them undoubtedly was that the main influence of the whole medical profession, which had been usually employed in favour of Liberal candidates and a Liberal Government, was, on this occasion, for reasons which are worth attention, used for the Conservative candidates. All the leading organs of the medical profession, which, on many political topics, exhibit a considerable

diversity of opinion, had been unanimous for many months in expressing the most decided disapproval of Mr. Stansfeld's administration of the Public Health. Animated by jealousy of the efficient staff of the medical department handed over by the Privy Council to the Local Government Board, the old officials of the Poor Law Board had persuaded Mr. Stansfeld very early in his career to show his independence by snubbing Mr. Simon and his staff, by first framing and then endeavouring to administer the Public Health Bill, 1872, without reference to them. The result has been the creation of a chaos of sanitary districts, officers, and proceedings which are the dismay of all who have watched with understanding eye the extraordinary vagaries of the poor law inspectors, in their character of sanitary envoys. One after another has gone forth with the most crude and variously elementary notions of his work; and one after another has floundered into the bog. The most able of them, Mr. Doyle, after completely breaking down in South Wales, has fairly fled. Mr. Henley appears only lately to have discovered that he really is not an authority on water-closets. About a thousand medical officers have been appointed, some over areas of a hundred thousand square acres, with a population of 250,000, and without any deputies or assistants; some over areas of one or two hundred acres; some with a small fee 'per case,' and a hint not to make cases, as their boards object to fees. The hopeless, heterogeneous, and ludicrous confusion which Mr. Stansfeld has brought about is deeply discouraging to those who looked to him to use the great opportunity of 1872 for establishing order, and at least laying down satisfactory lines. The obstinacy with which Mr. Stansfeld blundered into the bog of despond, and the discredit which he has brought upon sanitary legislation, have been the source of continuous comment in the medical press, and his determined effort, after disarranging the sanitary machine, to smash the index by crushing the medical department which was the witness and standing reproach of his blundering, roused the indignation of the entire profession, and lost the government a great proportion of votes in every constituency. The very cavalier manner in which Mr. Cardwell disposed of the grievances of the army medical officer, by concessions which are considered to be purely illusionary, did something to increase the medical discontent which threw the main influence of the British Medical Association with its 5,000 members into the hands of the Tories, and made the leading medical men of half the villages in Great Britain—and very often the doctor is a leading local politician—active agents for the Conservative candidates. Mr. Disraeli has with this party, at least, the advantage that his motto is *Sanitas Sanitatum*, and that Mr. Stansfeld's successor can hardly fail to enjoy a relative popularity with the main instruments and chief authorities of public health.

THE NUNS OF ST. JOHN'S SISTERHOOD.—A good deal of feeling has been excited in many circles in London by the rather summary determination, at which the Board of King's College Hospital have arrived, to give notice to quit to the Sisters of St. John's House, who have now for some years undertaken the nursing in that hospital. This step is taken on alleged administrative grounds, the medical and surgical staff, with one exception, being, we believe, entirely opposed to any such measure, on the ground that in the hands of the Sisters of St. John's House the nursing of the patients has been conducted with very great skill and tenderness, and that the example of nursing by ladies in sisterhoods, which King's College Hospital was one of the first to set, has been followed with advantage by most of the Metropolitan hospitals. A general meeting of governors, is, we believe, likely to be called to discuss the proceedings of the board.

INSTRUCTION OF MIDWIVES IN HUNGARY.—In 1872, the Hungarian Government instituted schools for midwives in Presburg and Grosswardein, and, having regard to the various languages and dialects spoken in the country,

ordered that in the former place the instruction should be given in the German, Hungarian, and Slavonian languages, and at Grosswardein in Hungarian and Roumanian. Dr. Ambro, professor at the Presburg school, has just published a text-book for midwives in the Slavonian language. A Vienna contemporary reports that the work contains some useful instructions for midwives, as to the conditions of labour which render it necessary for them to call in medical assistance, and in other respects defines clearly the limits of their sphere of labour. They are informed, *inter alia*, that the public medical service of Hungary is soon to be placed on a more satisfactory footing; and that none but intelligent women, able to read and write, will be allowed to practise midwifery.

SANITARY ORGANISATION IN LOWER AUSTRIA.—A code of organisation for the Sanitary Government of Lower Austria has lately received the Imperial sanction. Each town possessing a separate municipality, and each political district, is to form a sanitary district, and to have a council of health. In towns the burgomaster, and in the country districts the chief government officer, is to be at the head of the Council, which is in each case to consist of representatives of the public, and of the medical profession, including the district medical officers for the time being. The Councils have to make yearly reports to the General Council of Health.

A CHARITÉ HOSPITAL MEDICAL SOCIETY has been formed in Berlin. It consists of the medical officers of the hospital and of the Pathological Institute and Dispensaries, and its purposes are the utilisation of the great stores of material afforded by these institutions, and the promotion of friendly intercourse among its members. At the first meeting, on January 15, Dr. Mehlhausen, the medical director of the hospital, was elected president. One of the rules limits the length of all papers to fifteen minutes, and of speeches made in discussion to five minutes, unless a longer time be allowed by a special vote of the meeting.

THE prize of 500 lire (20*l.*) offered by the editors of *Lo Sperimentale* for the best paper published in that periodical during the year, has been awarded by the Medico-Physical Society of Florence, to which the adjudication is intrusted, to Professor Philip Pacini, for an elaborate essay on osmosis and absorption in the animal organism. The essay appeared in the numbers for October, November, and December of last year, and occupies altogether 169 pages of *Lo Sperimentale*.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 17*s.* 4*d.*; free by post, 19*s.* 6*d.*

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19*s.* 6*d.* Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUART.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, FEBRUARY 18, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

SPICER ON PARASITIC FLIES.

The following, by Mr. W. W. Spicer, of Itchen Abbas, is taken from *Hardwicke's Science Gossip*. 'By this term I do not mean the hosts of black flies, sand-flies, gnats, mosquitoes, *et id genus omne*, which try men's patience and temper by sucking their blood; but a still worse "crew," whose mission it is to deposit eggs either upon or within the human body. In these cases it is the larva or grub which works all the mischief. The period of occupancy occurs before the perfect insect comes to light; and therefore man's tenant, in the instances to which I allude, is the grub—not the fly.

Fig. 1. "Whorbles," or "Worm-holes," in hides of oxen.

'The last place perhaps in which one would look for the larva of a flower-fly (I know no better way of rendering the technical name, *Anthomyia*) is the human stomach. Yet at least two species (*scalaris* and *canicularis*) occasionally occupy this singular locality. How can they get there? is the first and most natural question; but one which it is by no means easy to solve. The most probable suggestion is that they are introduced with vegetables which have been standing for some time, and on which the mother-fly has, in the innocence of her heart, laid a batch of eggs, unwitting of the evil consequences likely to follow. But in whatever way they have been brought into their temporary lodgings, they appear to adapt themselves readily to surrounding circumstances, and to make themselves quite at home, clinging to the inner surface of the intestine by means of minute spines with which the back and sides are armed. While there, they cause, as may be supposed, considerable irritation.

'The occupation of the flesh-fly is more legitimate than that of those just named, and the insect seems to be but fulfilling its proper mission when it occasionally assumes the rôle of the parasite. It is true, its feeding-ground is more generally the dead than the living subject; still it is not averse, when the occasion offers, to choose man as the nidus on which to deposit its eggs or larvæ (for several species are viviparous), and to rear its young. In this way it has often caused serious annoyance and even danger to life, laying its eggs in hot weather on wounds and

sores, where they speedily hatch, and the grubs, instead of dropping to the ground, eat their way into the flesh. A terrible story is given by Kirby and Spence (*Introduction*, vol. i. p. 137, ed. 4), of a beggar being almost literally devoured alive by the larvæ of flies, attracted by some meat placed by the wretched man "betwixt his shirt and skin."

Fig. 2. Grub of *Hypoderma*.

Fig. 3. Flesh-fly (*Sarcophaga carnaria*).

'A similar story of a not less painful nature is recorded by M. Aristide Roger, in his *Les Monstres invisibles* (p. 55). It has reference to the death of a chiffonier, who was found a few years ago in a ditch just outside Paris, still living, but with his features completely destroyed by the multitude of blow-fly grubs feeding on him.

'Man's perverse ingenuity has converted this propensity of flies to devour living flesh into an instrument of torture; for Plutarch assures us, that in Persia state criminals were sometimes thus punished. For this purpose the wretched individual was fixed securely between two boats, the upper being inverted over the lower, with only the feet, hands, and face exposed; the latter being besides smeared with honey. The result may be imagined. Countless swarms of scavenger flies, attracted by their prey, deposited masses of eggs on the victim, who was

Fig. 4. Blow-fly (*Calliphora fulvibarbis*).

thus eaten alive. Persons have been known to live for several days before they succumbed to this horrible torture.

'The principal parasites, at least in this country, are the different kinds of flesh-fly (*Sarcophaga*, fig. 3) and blow-fly or blue-bottle (*Calliphora*, fig. 4), the prolific parent of the "gentles," dear to the heart of youthful Izaak Waltons. Prolific indeed they are! Degeer calculated that a single flesh-fly may deposit about fifty larvæ (for she is viviparous), and in the course of six months may become the happy mother of more than five hundred million descendants! (Lennis, *Naturgeschichte des Thierreichs*, s. 620.)

'In addition to the above there are two flies, whose habits have not been thoroughly studied, but the

effect of whose parasitism is, in one case at least, very serious. They are confined to the warmer regions of America, and are known to the natives under various names: in Brazil they are the Ura; in Costa Rica, the Torcel; in New Granada, the Gusano peludo; in Cayenne, the Ver macaque. With regard to one of these flies, Bates speaks as follows. "A species of *Æstrus* or gadfly, on the Upper Amazons, fixes on the flesh of a man as a breeding-place for its grub. I extracted five at different times from my own flesh. The first was fixed in the calf of my leg, causing there a suppurating tumour, which (being unaware of the existence of this *Æstrus*) I thought at first was a common boil. The tumour grew, and the pain increased until I became quite lame, and then, on carefully examining the supposed boil, I saw the head of a grub moving in a small hole at its apex. The extraction of the animal was a difficult operation, it being an inch in length and of increasing breadth from head to tail, besides being secured to the flesh of the inside of the tumour by two horn-hooks. An old Indian of Ega showed me the most effective way of proceeding, which was to stupefy the grub with strong tobacco-juice, causing it to relax its grip in the interior, and then pull it out of the narrow orifice of the tumour by main force." (*The Naturalist on the Amazons*.)

Alexander von Humboldt had already published an account of a fly with similar habits, which he named *Æstrus hominis*. According to his observations, the larvæ of the insect are not rare on the arms, back, and abdomen of the natives, within large tumours, at the top of which is a minute orifice, through which the grub communicates with the outer air. At a fitting period the larva forces its way through this hole, falls to the earth, and there undergoes its final changes.

All this is precisely what occurs in the case of the European gadflies. Every resident in the country must have noticed lumps or swellings on the backs of oxen, especially of heifers, which are called by the rustics whorbles (fig. 1) or wormuls, no doubt meaning worm-holes. Within each of these swellings lies ensconced a grub, the produce of a large brownish fly, which was named by Bracy Clark *Hypoderma bovis* (fig. 2). From August to May the head of the little creature is plunged in a mass of purulent matter, on which it feeds, while the tail, in which the breathing apparatus is situated, is thrust through a minute hole at the apex, in order to come in contact with the outer air. During the month of May the larva manages to enlarge the orifice, through which it drops to the ground and seeks a convenient place of shelter.*

This little bit of life-history points to a close analogy between our gadfly and the human parasite of South America. Moreover, a connecting link is found in a narrative given us by Don Ramon Paez in his *Life in the Llanos of Venezuela*, wherein he writes: "Agapito, our host, had an easy time as overseer of this domain, his only occupation being from time to time to scour the savannah in search of young foals which might have been attacked by the 'gusano.' This is the larva of a species of fly deposited in the umbilical cord of the new-born foal

which, if not promptly removed, will eat into their very vitals."

It will not escape observation that the horse-fly of Venezuela and the human parasite of the neighbouring state of New Grenada both pass by the name of Gusano.

On the whole, we can scarcely avoid the conclusion that some species of ox-fly not unfrequently leaves its proper pasture-ground, and deposits its eggs on the human frame. Certainly Van der Hoeven (*Handbook of Zoology*, i.) is inclined to think that the injury is due to this cause, or else to some species of *Tachina*.

Other authorities, however, introduce us to a fly whose mode of action bespeaks it a place among the flesh-flies—a group very far removed from the gadflies.

One species infests the valleys of Mexico, both North and South, though not found on the high table-lands. This fly lays its eggs in the nostrils of human beings; the larvæ are quickly hatched; and then follow rapidly ulceration, erysipelas, and meningitis. The insect gradually eats its way into the mouth, eyeballs, cheeks, &c., until in a fortnight or three weeks the miserable victim succumbs to his fate (*Archives médicales Belges*, 1867). The same or a similar plague is not uncommon farther south. Captain Burton does not appear to have been himself cognisant of any case in Brazil, but he speaks of hearing "many tales told of negroes losing their lives in consequence of the grub being deposited in the nose and other places" (*Highlands of the Brazils*). A more detailed account I translate from M. Girard's work, *Les Métamorphoses des Insectes*, published in 1867. "Since the transportation of prisoners condemned to hard labour to Cayenne has been in vogue, several fatal cases have been traced to the

Fig. 5. *Lucilia hominivorax*.

Fig. 6. Grub of ditto.

operation of a fly named by Dr. Coquerel *Lucilia hominivorax* (fig. 5). Other convicts have escaped with the loss of their nose; for it is into the nose and cheeks of sleeping men, especially when in a condition of helpless intoxication, that the insect introduces its eggs. The maggot, which is furnished with strong hooked mandibles, establishes itself in the interior of the nostrils, and in the frontal sinus; from thence it passes to the eyeballs, and causes gangrenous wounds in the eyelids; or it enters the mouth, and gnaws away the gums, the palate, and the pharynx, causing intense anguish. The patient experiences at first an itching sensation in the nostrils, accompanied by severe headache and swelling of the nose, which is soon followed by ulceration of the parts affected, during which the larvæ force their way through the skin, and make their appearance

* No great harm follows from the attacks of the gadfly to our herds; but we are told by Dr. Bernard Altum, in his lately published work, "Forst-Zoologie, Säugethiere," that in Germany the hides of the wild deer are often so riddled by these grubs as to render them unfit for the purposes of the tanner.

on the surface. As the evil advances, violent inflammatory action sets in, with all the symptoms of meningitis and erysipelas, until death releases the victim. The grub in question is known in Cayenne as the *ver macaque*, and was published to the world so long ago as 1735 by M. Arture, physician to the King of Cayenne. It is probable that the *ver moyacuil* of Mexico, which attacks men and dogs, is an analogous species.

“Dr. Coquerel has also made known another fly under the name of *Idia bigoti*, indigenous in Senegal, which stings the soldiers on duty near the coast. In all likelihood this stinging is the introduction of the animal's ovipositor previous to placing its eggs under the skin. The larva has been met with in tumours in the back, arms, and legs. The negroes are often attacked by this fly, and are skilled in extirpating the larva.”

‘From what has been related, and from the cases of assault quoted by Moquin-Tandon in his valuable *Medical Zoology*, I infer that at least two species of fly, belonging to distinct groups of the Dipterous order, are concerned in this kind of parasitism. One, an *Æstrid*, to be ranked with the European *Hypoderma*, causes swellings and sores on the legs and arms of the persons affected. This is probably the *Cuterebra noxialis* of Goudot. The other, a *Muscid*, nearly related to our blue-bottle (*Calliphora*), attacks the face of its victim: it is the *Lucilia hominivorax* of Coquerel.’

DISEASES OF CHILDREN.

ON DIABETES MELLITUS IN CHILDREN.

BY DR. HIRSCHSPRUNG OF COPENHAGEN,* WITH CASES BY DR. BUDDE OF COPENHAGEN,† AND DR. SCHOUBOE OF KALLUNDBORG.‡

In a former number of THE LONDON MEDICAL RECORD (March 12, 1873, p. 153) an abstract was given of a paper by Senator on diabetes in a child. Since then, Dr. Hirschsprung, of Copenhagen, has published a case, and has added some comments founded on it and on eleven other recorded cases; and cases have also been related by two other Danish physicians, Dr. Budde and Dr. Schouboe. The rare occurrence of the disease in children gives interest to these observations.

Diabetes, says Dr. Hirschsprung, is an especially rare disease in children. In vain we seek for a knowledge of it in the most celebrated authors on children's diseases, such as Rilliet and Barthez, Trousseau, Barrier, Vogel, Gerhardt, Steiner, Henoeh, &c., and those who give an account of it (Billard, Bouchut, Underwood) adduce no instances from their own experience, but cite an apocryphal case of the last century, attributed to Morton. The only author who speaks of the disease from his own observation is West, and he first mentions it in the fifth edition of his well-known work on the *Diseases of Children*. For a number of years he had not met with a case of the disease, and he relates that Prout, in 700 cases, found one in a child five years old, and twelve in persons aged between twelve and twenty. If

information on the subject be sought in monographs, it is very limited; and the discrepancies in the accounts given are so great, that the observations must be inaccurate on one side or the other. Bouchardat says that no age is free from glycosuria, that he has seen it in a child under three years of age, and in old men aged more than eighty, that the prognosis improves with age, and that he has not seen a case successfully treated under the age of fifteen. On the other hand, Durand-Fardel states that the examples of diabetes in children which have come to his knowledge, led him to believe that the disease is not very dangerous in them, that it is more easily treated in childhood than after puberty, but that the prognosis again improves with increasing age.

To arrive at any trustworthy information as to the behaviour of diabetes in children, we must refer to journalistic literature: this, however, contains but few published cases; and even these may be still further reduced, if we take those only which afford guarantees of an accurate diagnosis. Their number is so small, that a short abstract of them may be given.

1. Brown (*Virchow's Jahresbericht*, 1870, vol. ii.) relates the case of a female child, born of healthy parents. When one year old, she was weaned, and was afterwards fed mostly on farinaceous food. She had good health up to the age of twenty months, when she began to drink unusually much, and to pass urine often, especially at night. Five or six weeks afterwards, she became weaker and somewhat wasted. As the mother observed that the drops of urine on the floor left on evaporation a white substance which had a sweet taste, the urine was examined, and was found to have a high specific gravity and to contain an abundance of sugar. Emaciation, debility, erythema around the vulva, and a smell as of chloroform in the breath, were observed, and the child died in three weeks of exhaustion. On section, miliary tubercles were found.

2. Gelmo (*Jahrb. für Kinderheilkunde*, 1861). The patient was a girl aged six. There were slight indications of the presence of rickets at an earlier period. She had had hooping cough, scarlet fever, and measles; the last when she was five-and-a-half years old. From that time, she did not properly recover her strength. When Gelmo saw her in September, 1859, she was remarkably thin, pale, and depressed, and the skin was dry. The mother stated that for some weeks the child had had a voracious appetite, drank much, and passed urine often; and that there was involuntary discharge of urine at night, which had not occurred in previous years. The urine was found to have a specific gravity of 1.035, and to contain eight per cent of sugar. Two days later the child was collapsed and somnolent; she complained of obscurity of vision, had less thirst, and passed a smaller quantity of urine, which contained 5 per cent. of sugar. On the fourth day she lost consciousness. The urine, which was in small quantity, was of specific gravity 1.036, and contained 8 per cent. of urea and 15 per cent. of sugar. Death occurred on the fifth day. The head only could be examined *post mortem*. No collection of fluid was found in the ventricles, but the white substance of the brain was distinctly hypertrophied and anæmic.

3. Heiberg (*Ugeskrift for Læger*, 2nd series, vol. xxiv). A girl nine years old, previously healthy, had for six months frequently suffered from transient

* *Ugeskrift for Læger*, third series, vol. xv. no. 25.

† *Ibid.*

‡ *Ibid.* no. 30.

gastric symptoms. After the last attack there was some languor and wasting, but not much pallor; her face had some expression of suffering, and her temper was changeable. She had apparently recovered, when her condition became distinctly worse. It being stated that the child had lately often wet her bed, the urine was examined, and was found to contain 8 per cent. of sugar. She had not had much thirst, and had not passed urine often, but had lately occasionally done so at night. Five days after the diagnosis was made, the child died collapsed. At the necropsy, nothing was found which could explain the illness or its sudden termination. The brain was not examined.

4. Ingerslev (*Hospitals-Tidende*, 1869). A girl aged five years grew very thin in the course of two months, became fretful, and suffered from slight gastric disorder, generally attended with constipation; she had much thirst, and daily discharged an increasing quantity of urine. It was found to have the characteristics of diabetic urine, and contained a considerable amount of sugar. The treatment ordered was not carried out; and two or three weeks after Ingerslev first saw the patient, she died comatose, without having presented any new symptoms.

5. Seegen (*On Diabetes Mellitus*, 1870). A girl aged twelve came under observation on May 18, 1862. Her brother had died of diabetes a year previously. At the age of two-and-a-half years she had severe symptoms of diabetes, and took without effect various remedies. The percentage of sugar was 9.5. From this she recovered sufficiently to be able to go to school. In the winter of 1861-62 a cataract gradually formed in the left eye. The child now became very thin, pale, and low-spirited; she entirely lost vision in the left eye, the right remaining unaffected. The liver was normal. There was slight dulness at the apex of the lung. She had moderate thirst, slept well, and had a good appetite. She passed 3,450 cubic centimetres (more than six pints) of urine daily; it contained 8.2 per cent. of sugar. Ten days later the quantity was 2,900 cubic centimetres (about five pints), and sugar 6.8 per cent.; and these proportions continued as long as she was under treatment. Her diet was almost entirely animal. The strength did not perceptibly improve. In the following winter she died at her home.

6. Seegen (*loc. cit.*). A girl aged eleven, whose mother had mental disease, had suffered much from nervous headache, and for a long time had had much thirst, and had become very languid. In August, 1864, diabetes was diagnosed; she had then become very thin and pale, her skin was dry, a sour smell proceeded from the mouth, and the teeth were beginning to be carious. From four to seven potsful of urine, containing 7 to 7½ per cent. of sugar, were passed daily. The symptoms improved a little under the use of bicarbonate of soda, a rigid animal diet, and cod-liver oil; the weight of the body increased, and the amount of sugar diminished. On March 1, 1865, she became worse, and on July 13 came under Seegen's care. She was thin and pale; her head was large in proportion to the body, and her manner was shy and anxious. She had excessive thirst, and a voracious appetite; she was constipated, and was readily exhausted by slight exercise. Her weight was forty-nine pounds (Danish). She was under treatment from July 13 to August 24, during which time the amount of urine remained a little under 2,000 cubic centimetres (three-and-a-half pints), while the percentage of sugar fell from 4.9

to 3.9. The weight of the patient remained unchanged. The further course of the case is not related.

7. West (*Diseases of Children*, 5th edition). The patient was a girl aged three-and-a-half years. A brother aged two years, and a sister aged two-and-a-half, were said to have died with similar symptoms, six weeks after the commencement of their illness. Within about two months the child had been indisposed; she had become much emaciated, but had not manifested the violent thirst which is special to diabetes. The quantity of urine passed in twenty-four hours was about 4,000 cubic centimetres (about seven pints); it had a specific gravity of 1.045, and was found by the potash and Trommer's tests to contain an abundance of sugar. As the parents gave up all hope on the death of their other children, and could not be induced to try dietetic or other treatment, nothing more was known of the progress of the case.

8. West (*op. cit.*). This patient was seen twice only. It was a child ten years old (sex not stated), who for eighteen months had had symptoms of diabetes, which had followed convalescence from measles. The urine was abundant, and had a specific gravity varying from 1.035 to 1.050. The thirst, diuresis, and wasting were diminished by appropriate treatment.

9. Senator (*Berliner Klinische Wochenschrift*, no. 48, 1872). A weakly boy, aged thirteen, who had previously often been in bad health, had for some time suffered from enuresis and pain in the region of the bladder, without any other manifest symptoms. Belladonna was given without effect; the patient became steadily worse, and had great appetite and thirst. The quantity of urine passed daily was two or three quarts: it contained 3.2 per cent. of sugar. The almost complete restriction of the diet to animal food, and the internal and external use of alkalies, juniper, arsenic, and other remedies, were without avail; fever soon set in, with caseous bronchopneumonia, and death occurred in three weeks. The necropsy, which had to be limited to the abdomen, revealed nothing worthy of note.

10. Senator (*loc. cit.*). A girl, twelve years old, sparingly nourished and scrofulous, had for eight or ten days felt dull, and complained of violent thirst. Examination of the urine discovered a large amount of sugar. Fever soon appeared, and was followed in ten days by death, four weeks at most after the symptoms first became apparent.

11. Hauner (*Casper's Wochenschrift*, 1850). An illegitimate female child, one year old, was received into the Children's Hospital at Munich. It had been healthy at birth; but, as it had not been fed from the breast, but fed with milk gruel, it did not thrive, had diarrhoea, and manifested some symptoms of mesenteric disease. It was soon observed that the child drank very greedily, was constantly wet with urine, was very restless until it had allayed its thirst for a short time, and had a constantly dry skin. The urine, on examination, was found to contain albumen and unmistakable evidence of sugar. Treatment by animal diet, Gellnau water, and morphia had only a temporary effect, and the child died in a month, emaciated to the highest degree. At the *post mortem* examination, the kidneys alone presented signs of disease; they were enlarged and twice the normal size, and were of a whitish-grey colour and firm consistence; small purulent foci were found here and there in their tissue. The

mucous membrane of the pelves and ureters was in a state of catarrh.

Various other cases will be found reported in journals under the name of diabetes ; but their title to be reckoned as such is not sufficiently established by an accurate record of chemical analysis. There is specially room for doubt, whether some of the reported cases were not instances of diabetes insipidus, a disease which, according to some authors (Hauner and Roger) is not more rare in children than in adults, and may be followed by death. To the eleven cases above mentioned is limited the entire number of unquestionable cases of diabetes mellitus in children which I have been able to find in literature ; but, although the number is small, and some of the narratives in their original form do not indicate that the cases were subjected to minute examination, they yet give valuable information on some important points. In the first place, we see that the disease may occur at various periods of childhood. The etiology is as uncertain in children as in adults ; we see the disease occur in children living in good circumstances, but it seems especially liable to occur when nutrition is defective. In no case was there evidence of hereditary tendency, although in two cases the disease appeared in brother and sister. In two cases the disease was developed during convalescence from measles. Very remarkable, if not accidental, is the frequency with which the disease occurs in girls. Of eleven cases, nine were in females, one in a male, and in one the sex is not stated : and in my own observation the patient was a girl. [It will be seen that in Dr. Budde's case, to be afterwards treated, the patient was a boy ; and in Dr. Schouboe's case, a girl]. If this relation should prove to be constant, it will be the reverse of what occurs in adults, where males are most liable to the disease.

The symptoms are altogether the same in the child as in the adult ; but in some cases attention has first been directed to the disease by the occurrence of nocturnal enuresis in children at an age above that at which the symptom usually appears (Senator). Cataract is mentioned in one case, gangrenous affections in none. It is difficult to estimate the duration of the disease, as the time of its commencement is often unknown : sometimes the patients have died in a few days or a fortnight after the disease has been first observed, especially in very early age ; in older children, the influence of remedies has been greater and the duration of the illness longer. Just as the symptoms resemble those in the adult, so do the results of the *post mortem* examinations, in the few cases in which they have been made ; the appearances are either negative, or such as may be considered as secondary. The second case only (Gelmo's) is an exception, inasmuch as on careful investigation there was found to be hypertrophy of the encephalon—the relation of which to diabetes may, however, be regarded as doubtful.

(To be continued.)

UNIVERSITY OF VIENNA.—It has been decided, we understand, to institute a professorship of experimental pharmaco-dynamics in the University of Vienna. The *Wiener Medizinische Wochenschrift* cannot recognise the necessity for this chair, seeing that the university has already a professor of pharmacology, who teaches the action of drugs at the bedside or by experiments.

MILITARY MEDICAL OFFICERS' SOCIETIES have been formed in Vienna and in Pesth.

CLINICAL MEDICINE.

ABSTRACT OF A CLINICAL LECTURE ON METEORISM. BY THE LATE PROFESSOR OPPOZLER, OF VIENNA.*

(Concluded from p. 50.)

Having in the previous remarks briefly treated of the etiology of meteorism, we will now consider the treatment.

While, on the one hand, in spite of the great number of opinions which have been formed in the course of ages on the etiology of meteorism, it has been quite impossible to bring to light its true nature, and even Oppolzer's probable theory, that the condition has its beginning and end in the nervous system, requires more accurate proof and complete elucidation ; on the other hand, the rational treatment of meteorism has to encounter less numerous and no smaller difficulties. This is explicable, when we find in the most various quarters innumerable medicines mentioned as efficacious against this morbid symptom, as is no less the case with many other diseases, while yet not one or other of them is capable of even approximatively fulfilling the required conditions.

Starting with the view that meteorism depended on a paralysis of the nervous system, Oppolzer was directed by this assumption as to the course to be followed in combating the symptom described, so far as it was within the power of medicines. He adapted his experiments solely to the opinion which he had formed, and, in prescribing, gave special preference to medicines capable of stimulating the nervous system.

In the milder cases of meteorism, he for the most part employed friction of the abdomen with Hoffmann's balsamum vitæ, carminative ointment, or spirit of camphor ; the last of which seemed to him often the most effectual means of favouring the escape of gases and thus reducing the distension of the abdomen. Notwithstanding that, on the whole, this treatment was attended with as much success as was possible, it became evident that along with the action of the remedies described was combined that of friction ; and Oppolzer for some time desisted from inunction, employing friction alone as a means of stimulating the nervous system. It is self-evident, that inunctions can only be used in cases where there is no erysipelas of the abdominal wall.

Other remedies usually employed in cases of this kind are the carminatives, which act as stimulants of the nervous system. Oppolzer, however, was not a great friend of carminatives, as all more or less affect the head, and thereby bring more or less trouble to the patient. He generally used them only in cases where cold applications were no longer well borne.

When no good result could be obtained from these means, or when their use was contraindicated for special reasons, Oppolzer made abundant use of cold compresses, or, when these could not be borne, of warm moist ones. He held very strongly to cold compresses, and used them in special preference and with fortunate results. It must be remarked of cold bandages, that their use, when meteorism has reached a high degree, is indicated on the special ground that they are far more useful in exciting the intestinal

* *Allgemeine Wiener Medizin. Zeitung*, January 27 and February 3, 1874.

movements than any of the other remedies. In applying them, it is advantageous at first to use water which has stood some time in the room, and gradually to pass to cold water, and then to ice-water and bladders of ice. The cold compresses, as used by Oppolzer, are soaked for some time in water, then wrung out, and laid on the abdomen, being covered with a layer of gutta serena. In general, however, they are badly borne by the abdominal wall; they are, however, an excellent remedy even in peritonitis. Their action, although it does not take place in all cases, consists in exciting the movements of the intestines. The escape of gases and the disappearance of meteorism may often be observed under their use. The distressing feelings which attend meteorism are also removed by the cold compresses, through the use of which the gases are condensed; the dyspnoea, however, which attends a high degree of meteorism is not relieved by them, as meteorism in this stage does not yield to either cold or warm compresses.

Oppolzer further observed, that peristaltic movements of the intestines, followed by evacuations, were produced by simply rubbing the limbs with cold water. A small quantity of vinegar may be added to the cold water in which the compresses are dipped, to increase the desired action.

A further remedy that has been used against meteorism, is the administration of clysters. Oppolzer used these only for the purpose of stimulating the rectum; and under their employment he has observed a discharge of faeces and gas to take place, followed by descent of the diaphragm, increased ease of respiration, and relief of the dyspnoea to some extent. Castor-oil was generally added to the enemata, and for the most part did good service; but if it were desired to increase its action, more vinegar was added; this, however, can only be used in small quantity, as it has been known to readily set up inflammation of the rectum. Oppolzer's usual formula for enemata consisted of a spoonful each of vinegar and castor oil, and a pint of water. Cold water and camphorated spirit may also be used.

The attempt has also been made to relieve meteorism by evacuating the intestines of gases by introducing a tube. When it is possible to reach the part of the bowel containing the gases, these indeed escape, and the meteorism is thereby removed; but if the tube reach a part filled with faecal matter, its orifice is blocked up, so that no gas can escape.

A further endeavour has been made to pump out the gases by a piston, applied to the tube which is introduced into the bowel; but here also the apparatus can only act when the tube is in the intestine containing air, otherwise the faeces obstruct the end and prevent the passage of gases. In such a case, the attempt has been made to push the tube beyond the part of the intestinal canal where the faeces are contained: and if a passage be thus made and the piston drawn out, gases will escape. But it may readily happen, that the mucous membrane of the intestine passes into and blocks up the upper end of the tube, and may thus be forcibly drawn into it. Such an occurrence is very dangerous, as it may give rise to inflammation of the mucous membrane; in some cases, indeed, pieces of the mucous membrane have been torn off, giving rise to the formation of ulcers.

Setting aside the fact, that the pumping out of gases from the intestines must always be regarded as an essentially dangerous undertaking, it is further not always effectual; and indeed it is never neces-

sary to use the piston, seeing that the mere introduction of the tube into the part containing gases allows their escape, without producing injury of the mucous membrane.

The notion—theoretically correct—has also been entertained, that the gases—such as carbonic acid, sulphuretted hydrogen, and carbonate of ammonia—contained in the intestinal canal, might be fixed by appropriate chemical substances; and the most various experiments have been made in this direction. Thus the endeavour has been made to fix the carbonic acid by administering enemata containing calcined magnesia, the sulphuretted hydrogen by clysters containing salts of iron, zinc, or lead, and the carbonate of ammonia, which is specially collected in the intestines in typhus fever, by enemata containing chlorine, so as to form chloride of ammonium.

In very severe cases of meteorism, where it has not been found possible to remove the gases by the introduction of a tube, the caecum has been punctured. This expedient is, however, a doubtful one; since it is generally difficult to reach the bowel, which has a tendency to slip aside from the instrument. If, however, one have the good fortune really to penetrate the bowel with the instrument, the muscular fibres will contract around and close the opening on its removal, so that no more air can escape. On the other hand, if the bowel have lost its contractile power—and this is very often the case in consequence of its becoming paralysed—nothing can be gained by puncture, for the bowel cannot contract. In such circumstances, the faeces will escape through the opening into the abdominal cavity, and set up peritonitis.

When, therefore, the intestine is paralysed, puncture should certainly not be attempted. But, as it is not easy to ascertain whether the distended bowel is paralysed or not, puncture should for this reason alone be avoided—unless one wish to trust to good luck for the success of the operation. Only when it is positively known that the intestine retains its contractile power, is it right to make a puncture.

Oppolzer performed puncture once, when young, with a successful result; but afterwards he could never resolve to repeat it. When relief has followed puncture, it has been only of very short duration.

Dry cupping has been alleged to excite contraction of the intestines; but Oppolzer never used it.

Electricity has also been brought into use in the treatment of meteorism; it acts chiefly on the abdominal muscles, and good results have been obtained from it. Where, however, acute ileus has set in, Oppolzer has never observed good effects to follow the use of electricity.

When compression and hyperaemia of the lungs have occurred in consequence of meteorism, and there are strongly marked cyanosis and dyspnoea, the best plan is to treat the symptoms, and perform venesection to relieve the pulmonary oedema. It is very evident that this can only temporarily remove the danger which threatens the patient's life; but there is no other means of producing even this temporary withdrawal of danger.

ANATOMY AND PHYSIOLOGY.

FOSTER ON THE EFFECTS OF A GRADUAL RISE OF TEMPERATURE ON REFLEX ACTION IN THE FROG.—Goltz observed that, if a brainless frog be

placed in a vessel of water, and the temperature of the water be very gradually raised to 40° Cent. (104° Fahr.), no movements (beyond a few flickering spasms) take place; the frog becomes at last perfectly rigid, and dies without any attempt at escape. Dr. M. Foster (*Journal of Anatomy and Physiology*, Nov. 1873, p. 45) has verified this statement, and asks why the brainless frog is not excited by the stimulus of the hot water. In addition, he has made the following observations.—1. If a frog, from which the brain has been removed, be suspended by the jaw with the legs hanging freely down, and the toes dipping into a vessel of water, on gradually heating the water the toes are withdrawn by reflex action as soon as the temperature of the water reaches a little over 30° Cent. The result does not essentially depend on the rapidity of the rise. However slowly the water be heated, the feet are always withdrawn at a temperature of 35° Cent., or earlier. Whether heated slowly or rapidly, the feet are withdrawn at about 35° Cent. or at a lower temperature.—2. If the whole body thus suspended be similarly immersed and heated, no movements (or only the very slightest spasms of the muscles of the legs) take place; and on still further raising the temperature the body becomes rigid (*rigor caloris*).—3. If both legs be immersed up to the anus, and similarly treated, they also become rigid without movements either of the legs or of any part of the body, save only a few spasms.—4. If one leg only be immersed and similarly treated, it also becomes rigid without movements, or with only slight movement.—5. If both legs (or one leg) be immersed up to the knee, they are sometimes withdrawn; but sometimes no movements take place, and the portion immersed becomes rigid. The results in this case are not so constant as when either more or less of the body is immersed.—6. If the feet only be immersed, they are invariably withdrawn at 35° Cent., or under.—7. If a frog be suspended over a vessel divided by partition, with water at unequal levels on the two sides, so that one leg is wholly immersed and the foot only of the other leg, and the vessel be surrounded with water, the temperature of which is gradually raised, neither the leg nor the foot will be withdrawn, if care be taken that the water on both sides of the partition be equally and uniformly raised in temperature. If in this last observation the water on both sides be reduced to the same level, both feet are withdrawn. The following observation shows clearly that, whether or not the stimulation of a large surface may assist in producing the effects described, the main cause is the heating of the spinal cord.—8. A brainless frog was so placed in a vessel with a hole in the bottom, that the body and forearms could be exposed to the action of water, the temperature of which was gradually raised, while the whole of both legs from the hips downwards hung freely from the vessel, and were not subject to the action of the heated water. Though in an unusual position, the frog remained quiet in the absence of stimulation, and executed reflex movements when stimulated so long as the water in the vessel above remained at the ordinary temperature; thus, when the toes were made to dip in water gradually warmed, the legs were drawn up after a while as usual. When, however, the temperature of water in the vessel above, and that in which the toes were dipped below, were both raised *pari passu*, no movements at all took place; and ultimately, as the temperature continued to rise, the body above and the toes below became rigid from *rigor caloris* (the legs and thighs remain-

ing supple), without any save the slightest spasm. Tested by the dilute sulphuric acid method (which was here practicable) the reflex excitability of the spinal cord diminished as the temperature in the vessel above rose, without any signs of an initiative stage of exaltation.

The author concludes that the absence of reflex action in Goltz's experiment and the other modifications of it, are due primarily and chiefly to the depressing influence of heated blood carried from the skin to the spinal cord. The absence of reflex action with a gradual rise of temperature is still further ensured by the stimulus being uniformly applied, and by the exposure to the stimulus of a large amount of sensory surface at the same time. Both these circumstances tend to put off the reflex action till a higher temperature is reached, and thus assist in preventing it altogether. [Vide *Nature*, Dec. 4, 1873, 'Sensation in the Spinal Cord,' by G. H. Lewes, and reply in *Nature*, Dec. 11, by M. Foster.]

DEW-SMITH ON DOUBLE NERVE STIMULATION.

Dew-Smith (*Journal of Anatomy and Physiology*, vol. viii.), applied two pairs of electrodes to a nerve (sciatic of frog, with the gastrocnemius attached), one pair (B) being nearer the muscle than the other (A). We have thus four different cases:—

Case I. where the current in A is descending, in B descending.

| | | | | | |
|------|---|---|---|----------------|------------------|
| II. | " | " | A | " | B ascending. |
| III. | " | " | A | A is ascending | in B descending. |
| IV. | " | " | A | " | B ascending. |

The majority of observations were made on Case I. Two separate and independent induction-machines were employed for stimulating the nerve, and the contractions of the muscle were registered by means of the pendulum myograph. With simultaneous stimulation of two different points of the nerve, the contraction resulting is the same as when the near point only is stimulated; but when a small interval of time is allowed to elapse between the two stimulations, the contraction increases, rising to a maximum as the interval is lengthened, and afterwards dividing gradually into two independent curves. The direction of the current makes no difference whatever to the general result, that with simultaneous double stimulation there is no increase of contraction.

YULE ON THE MECHANISM OF OPENING AND CLOSING THE EUSTACHIAN TUBE.—Yule (*Journal of Anatomy and Physiology*, vol. viii.), had a catheter passed into his Eustachian tube, in order to compare the sensations felt in the normal ear with those in the catheterised one. The author found that the sounds produced in the larynx were rendered very much louder. That the Eustachian tube opens during the act of swallowing, is well known. The mechanism of the opening of the Eustachian tube, when not complicated by swallowing, the author, experimenting upon himself, finds to be the following. First, during the contraction for opening the tube, the velum palati does not change either its position or its shape—in fact, it remains unmoved; and further, it does not become tense, but hangs as soft and flaccid to the touch as at ordinary times of rest. (The tensor and levator palati muscles do not, therefore, participate in the opening of the tube.) Secondly, the only parts which do move are the two posterior pillars of the pharynx: they both move inwards simultaneously towards the middle line, moving from their old position from one-half to three-quarters of an inch. This action is steady,

and not spasmodic, and can be sustained for some considerable time at will. (The muscles most evidently concerned are the palato-pharyngei.)

The sound which accompanies the opening of the Eustachian tube is sharp and crackling, and is referred to some part of the tympanum, or perhaps to the membrane itself. It can be easily imitated on the sheep. The author believes it to be due to the separation of the walls of the Eustachian tube. The author then gives an anatomical description of the muscles involved, and the manner in which they act to produce opening or shutting of the Eustachian tube.

WILLIAM STIRLING, D.Sc., M.B.

PERSONNE ON CHLORAL AND ITS COMBINATION WITH ALBUMINOID MATTER.—In a work on chloral presented to the French Academy and published in 1869, M. Personne showed by experiment, that the transformation of chloral into chloroform, as had been formulated by Liebreich, was actual. M. Personne now makes public fresh proofs of this change, which has been contradicted upon the ground that blood does not possess sufficient alkalinity to transform chloral into chloroform; for, say the objectors, this change cannot be effected by alkaline bicarbonates—Vichy water, for instance. But it is found that, besides strong or feeble alkalies, magnesia, alkaline salts, such as bicarbonate of soda, of potash, borate and phosphate of soda, all alkaline animal liquids, as blood and white of egg, cause the transformation of chloral into chloroform, when the mixture is carried to a temperature of 40° Cent. (104° Fahr.).

In order to explain the difference of physiological action that exists between chloral and chloroform (the action of chloral is of longer duration than that of chloroform) we must look to another product of chloral, formic acid, and assume that this acid furnishes the carbonic acid of which the hypnotic action aids that of the chloroform. It is known that the division of hydrate of chloral gives, per cent., 72.20 of chloroform, and 27.80 of formic acid, according to the equation: $C_4HCl_3O_2, H_2O_3 = C_2HCl_3 + C_2H_2O_4$; further, a greater or less portion of the chloroform can be separated in the presence of soda into formic acid and chloride of sodium, $C_2HCl_3 + 4NaO = C_2HNaO_4 + 3NaCl$. A portion of the formic acid is certainly eliminated with the urine; but, admitting that the whole of the formic acid produced by the complete destruction of the chloral may be transformed into carbonic acid, is it to be supposed that the action of the carbonic acid aids that of the chloroform? The following reasons would indicate the supposition to be incorrect: 100 grammes of hydrate of chloral produce under complete decomposition 56 grammes of formic acid; consequently, 5.6 grammes is the weight of this acid that should be furnished by 10 grammes of chloral hydrate—a quantity that cannot be administered to a dog of medium size. But a dose of 10 grammes of dry formiate of soda, representing 5.83 of formic acid, administered to the same dog, does not produce the least anæsthetic effect.

But the following observations tend more completely to solve the question. Fresh blood, to which hydrate of chloral is added and maintained at the ordinary temperature, completely coagulates, and preserves its red colour, and remains unaltered (will remain so for months). When a small piece of muscle was plunged into a solution of chloral hydrate, its colour paled a little; a red liquid

exuded, which soon deposited a sediment. After several hours' immersion, the muscle left at a temperature of 15° to 20° Cent. (59° to 68° Fahr.), did not putrefy; it desiccated rapidly, taking a more vivid tint, and becoming friable, and easily pulverised. The dry matter contained some chloral and with alkalies furnished chloroform. Albumen also combines with chloral.

It is now generally admitted that albuminoid matters are amides; and, the aldehydes being susceptible of combination with these substances, it is not unreasonable to suppose that chloral, which is only a trichlorated aldehyde, can form with them analogous compounds. This combination of chloral with albuminoid matters will explain the longer duration of the action of chloral. The primary action of chloral hydrate upon albuminoid matters is to produce chloroform at the expense of the albuminoids; at the same time these matters deprived of their alkali, combine with the undecomposed chloral, and this combination affords a kind of reservoir of chloroform, gradually absorbed during circulation. This is explanatory of the occurrence of small quantities of chloroform in the blood of animals submitted to the action of chloral; it justifies the use of chloral in the dressing of wounds, as a powerful modifier of the tissues. It also shows that chloral can be advantageously employed for the preservation of the most alterable animal matters. M. Personne has preserved for some months a cerebellum placed in a solution containing one-tenth of chloral hydrate. Chloral hydrate can be employed in the preservation of a corpse, or of anatomical preparations.

APPLIED PHARMACY.

SIEBOLD ON THE DETECTION OF ARSENIC IN HYDROCHLORIC ACID.—Mr. L. Siebold (*Pharm. Journ.* [3] iv. 312), reports that arsenic is frequently present in commercial hydrochloric acid. He considers that the usual plan of boiling a little suspected hydrochloric acid with a piece of pure copper foil, although a convenient test, is not sufficiently delicate to detect very small traces of arsenic. A careful examination with sulphuretted hydrogen will often prove most unmistakably the presence of arsenic in hydrochloric acid which has appeared to be free from it by the copper test. It is not sufficient, however, to add a solution of sulphuretted hydrogen, but the gas must be passed through the acid until the latter is completely saturated. After twelve hours, the precipitate which will in any case be formed, must be filtered, washed, dried, and fused with carbonate and nitrate of sodium; the fused mass dissolved in water, filtered, mixed with pure nitric acid in excess, boiled, and then tested with ammonia and nitrate of silver, or with sulphuretted hydrogen. It is impossible to judge of the absence of arsenic by the light colour of the precipitate.

SIEBOLD ON THE PREPARATION OF PURE HYDROCHLORIC ACID FROM THE COMMERCIAL ARTICLE.—On the strength of numerous experiments, Mr. L. Siebold recommends (*Pharm. Journ.* [3] iv. 312), the following two methods for preparing perfectly pure hydrochloric acid from the crude commercial article. The first method yields an acid of low specific gravity (1.20 to 1.25), which, though very suitable for analytical purposes, does not come up to the pharmacopœia standard of strength. The crude acid diluted with sufficient water to reduce the specific gravity to about 1.12, is saturated with sulphuretted hydrogen gas, and allowed to stand for fully twelve hours. The clear liquid is then decanted from the precipitate, and after the sulphuretted hydrogen has been driven off by heat distilled from a little chloride of sodium. The sulphuretted hydrogen removes not only the arsenic, but likewise the free chlorine or the sulphurous acid, whichever of the two may be present.

The second method, proposed by A. Bettendorff, yields a pure acid of 1.16 sp. gr. with very little trouble indeed. The crude acid, the specific gravity of which should be between 1.16 and 1.18 (not lower than 1.16) is mixed with a small quantity of a solution of stannous chloride in hydrochloric acid of the same strength, and allowed to stand for twenty-four hours. Any arsenic present will thus be precipitated in the shape of a brown powder, which consists of metallic arsenic, and a variable amount of tin. Sulphurous acid, if present, is precipitated as stannous sulphite, and in filtering is removed with the arsenic. The filtered acid now only requires to be distilled from a little chloride of sodium, as in the previous process. But as hydrochloric acid of so high a specific gravity parts with a great deal of hydrochloric acid gas on boiling, it is necessary to place a little water in the receiver for its absorption. This method also removes free chlorine, if present. Although stannous oxide forms an extremely delicate test for arsenic, the simultaneous presence of sulphurous acid might lead an inexperienced worker into error.

SIEBOLD ON PURE SULPHURIC ACID.—Mr. Siebold reports (*Pharmaceutical Journal*, [3] iv.

313) that the chief impurities for which sulphuric acid should be tested before using it for medicinal or analytical purposes are arsenic, lead, and oxides of nitrogen. Arsenic is best detected by Marsh's test, lead by sulphuretted hydrogen, and oxides of nitrogen by ferrous sulphate. An acid free from arsenic and nitrogen oxides, but containing lead, calcium, iron, &c., may be easily purified by distillation, but this will not remove the first-named impurities. The acid should be mixed with six or seven times its volume of water, and the mixture saturated with sulphuretted hydrogen. After forty-eight hours, decant the clear liquid from the precipitated sulphides of arsenic and lead; evaporate in a retort until fumes of sulphuric acid escape, and then distil. What passes over first is too weak and should be rejected, until an acid of 1.84 sp. gr. distils. To assure a quiet boiling of the acid, and thus to prevent a cracking of the retort, it is extremely useful to conduct a slow current of air, by means of an aspirator, through the acid during distillation.

SIEBOLD ON PURE NITRIC ACID.—Many samples of nitric acid, sold as perfectly pure, are quite good enough for medicinal use; but the traces of sulphuric acid, which they almost invariably contain, are a source of annoyance in medical laboratories where the acid is required for accurate scientific investigation. Mr. Siebold states (*Pharmaceutical Journal* [3] vol. iv. 313) that the application of the Pharmacopœia test—the addition of solution of barium chloride to the diluted acid—is insufficient to detect very small quantities; but if about four ounces of acid be evaporated on a water bath until only a few drops are left, and the residue mixed with a little distilled water and a few drops of solution of chloride of barium, a precipitate will be obtained from any commercial specimen of 'pure' acid. Nitric acid of the utmost attainable purity may be obtained by distilling commercial acid of 1.42 sp. gr. of good quality with a little absolutely pure nitrate of potassium from a glass retort. What passes over first must be rejected, until an acid distils, which, if diluted with water, forms a perfectly clear mixture with solution of nitrate of silver, and remains clear after standing ten minutes. Not less than two drachms of the acid should be subjected to the test. When thus free from every trace of hydrochloric acid the receiver is changed, and the distillation carried on until only about one-eighth of the original bulk remains in the retort. If carried further, traces of sulphuric acid might pass over with the nitric. This method is one generally adopted for preparing pure nitric acid of the pharmacopœia strength, but in consequence of the distillation being carried too far, or impure nitrate of potassium being used, few specimens are found free from sulphuric acid. Mr. Siebold says, however, that the separation of sulphuric acid from nitric acid, even of so high specific gravity as 1.4 is not difficult, though its boiling point being very high, if the distillation at that temperature be carried too far, or too little nitrate of potassium be used, traces of sulphuric acid invariably pass over. But an acid of lower specific gravity, about 1.25, suitable for most analytical purposes, may be always thus produced perfectly free from sulphuric acid.

Another method of purifying nitric acid consists in removing the hydrochloric acid by the addition of solution of nitrate of silver to the somewhat diluted acid, decanting from the precipitate and distilling the clear acid with a little perfectly pure nitrate of potassium, until about seven-eighths have passed over.

This method is only applicable for preparing an acid of low specific gravity (1.25).

GROVES AND WILLIAMS ON THE PREPARATION OF HYDROCYANIC ACID.—A discussion having arisen at the meeting of the British Pharmaceutical Conference (*Pharm. Journ.* [3] iv. 314), as to the possibility of the substitution of a definite salt, such as the crystallised cyanide of potassium, for an equivalent quantity of hydrocyanic acid, Mr. Groves suggested the use of cyanide of zinc. This salt, unlike the crystallised cyanide of potassium, which is deliquescent and easily alterable, is perfectly stable, readily yields up its hydrocyanic acid to the acid juices of the stomach or to dilute mineral acids, and is, Mr. Groves thinks, worthy of consideration, if not of a place in the next Pharmacopœia. Mr. Williams recommended the addition of a mineral acid to hydrocyanic acid, since it is impossible to keep that acid when perfectly pure any length of time. He urged that an equal quantity of hydrochloric acid should be ordered to be added. Thus, he thought two per cent. of hydrochloric acid might be added to a two per cent. hydrocyanic acid solution, and the acid could be preserved longer in that way than in any other.

POCKLINGTON ON THE STARCH GRANULES OF JALAP, CALUMBA, SENEGA, AND RHUBARB.—Mr. Pocklington thus sums up the characteristics of the starch granules occurring in these pharmaceutical roots (*Pharm. Journ.* [3] iv. 353). The starch granules of jalap are large, vary much in size and shape, and are aggregated or isolated. The compound granules consist of three triangular granules, the bases of the triangles being curved; the resulting granule is muller-shaped, approaching the circular. Many of the single granules are nearly circular, flattened with a triradiate indistinct hilum. In calumba root the granules are also large and very variable, sometimes simple, generally compound. The simple granules vary from nearly circular to mussel-shaped; the compounds are usually muller-shaped. The normal form of hilum is a longitudinal furrow, but a simple point or a three or four radiate slit or furrow are, collectively, as frequent. This starch is exceedingly sensitive to the action of any medium in which it may be immersed, and disrupts under slight elevation of temperature. In senega root the granules vary from a very small sharp-edged polyhedric granule to one of considerable size, more round and flattened. In rhubarb, the compound granule is oval, and composed of four well-formed granules, each with a distinct hilum.

GREENISH ON THE BOTANICAL EXAMINATION OF TEA.—Mr. T. Greenish recommends the examination of suspected leaves to ascertain whether they present the marked botanical characteristics of the true tea-leaf (*Pharm. Journ.* [3], iv. 334). Water should be poured over them, and they should be examined individually. The serration and venation of tea-leaves are very characteristic, the serration only coming half way down the leaf, and the primary venation stopping short of the edge of the leaf, or rather turning off and leaving a distinct space between it and the edge of the leaf. At the apex of the leaf there is a notch instead of a point. Again, if the under cuticle of the leaf be removed, the characteristic distinct space between the two cells of the stomata will be perceived. It is important to bear in mind that the Assam tea-leaf has its margin biserrate.

PSYCHOLOGY.

LEIDESDORF ON SATURNINE EPILEPSY WITH PSYCHIC DISTURBANCE.—Dr. Leidesdorf relates (*Allgemeine Wiener Medizinische Zeitung*, Nov. 4) the case of a man twenty-five years old, who had suffered from an attack of colic which left behind a trembling state of the limbs. Eight days before his admission to the asylum he had eight epileptic seizures one after the other, and became much depressed, fearing to die if left alone. There was difficulty in putting him to bed, and he tore off his clothes and spoke incoherently. The usual signs of chronic lead-poisoning were present; the urine was alkaline, not albuminous, nor was there any kidney affection. For the most part he was unconscious, but occasionally had lucid intervals. After a few days the fits returned very frequently, he became comatose, an erythematous rash spread over the whole breast, and he died. The diagnosis was anæmia and œdema of the brain complicated with pulmonary phthisis, all confirmed by the necropsy. Neither in the membranes, brain-substance, vessels, nor connective tissue was anything abnormal found by the microscope, but on chemical examination a small quantity of lead was found in the urine and some sulphide and sulphate of lead in the brain. The symptoms closely resembled, by the general tremor, the quasi-stottish unconsciousness, the searching about on the floor, delirium potatorum, whilst the coma and amaurosis which followed the epileptic seizures might have led to a diagnosis of uræmia, if the paralysed extensors and the blue line on the gums had not indicated lead.

Since the psychic lesion and the epileptic attacks first appeared a year after the lead-colic, they must be regarded as quite independent of it, for, according to Desbois and Tanquerel, encephalopathia saturnina may attack persons who have never before suffered from lead-disease. Tanquerel has related six such cases out of seventy-two of lead-poisoning; and accordingly saturnine epilepsy is a special form of the diseases caused by lead-poisoning. It does not consist of a demonstrable anatomical change in the brain, but belongs to the class of brain-neuroses induced by poisoning. Traube, in 1861, set forth a hypothesis that lead-poisoning in the first instance affected the kidneys, and that uræmia following was the cause of the epilepsy. Although Tanquerel (the best authority on lead-poisoning) expressly declares that he never found albumen in anything like a sufficient quantity in the urine, yet Ollivier and Lancereaux quote cases of Bright's disease among those poisoned by lead. In order to settle the question, Professor Rosenstein experimented on dogs, which died in consequence of chronic lead-poisoning, together with saturnine epilepsy, and his results were published in *Virchow's Archiv* for 1867. He concluded that chronic lead-poisoning causes neither albuminuria nor intense anatomical changes in the kidney, that it ends life very often through attacks of epilepsy resembling uræmic attacks, especially as in both amaurosis is set up, and in lead-poisoning diuresis is lessened. In animals so destroyed, lead can be found in the brain. The diminution of urine-flow is an accompanying symptom, not a causative one, and the basis of the epilepsy is anæmia of the brain. Acute œdema of the brain was found twice by Rosenstein, and was twice absent; and Tanquerel found it a frequent, but not

constant symptom. Where it occurs it aids the anæmia, but cannot be viewed as the cause of it. How cerebral anæmia is caused by lead-poisoning is not clear; yet, from the proved deposit of lead in the brain, and (as Gusserow has shown), the considerable deposit in the voluntary muscles, the influence on the smooth muscular fibres and the brain-vessels should not be disregarded. Heubel, in his thorough experiments, intended to refute or confirm Gusserow, proves that next to the liver and spleen, which promote the excretion of lead from the organism, the largest accumulations of lead are found in the brain and spinal cord, and that it has a more intense affinity for nerve-tissue. He thinks, then, that lead directly affects certain parts of the peripheral or central nervous system, and enters into at present imperfectly known combinations with each part, and that the chronic symptoms, such as headache, loss of sleep, stupor, melancholy, weakness of memory, &c., are due to deposit of lead in the brain, and the acute symptoms are caused by œdema of the brain, and the induced anæmia.

Tanquerel has collected thirty-one cases of lead encephalopathia running an acute course; of these seventeen were uncomplicated with epilepsy, whilst fourteen were so affected, and amaurosis was only twice established in the first, but six times in the second class. Noteworthy in all the patients is the constancy of hallucinations of sight. In the more gradually developed forms, the cases of lead-psychosis resemble paralytic brain-diseases in the attacks of unconsciousness with or without convulsions, tremblings, weakness of memory, and paralyses. But melancholic and maniacal forms are also seen, and the furious outbreaks are, for the most part, due to hallucinations of a horrifying nature.

T. C. SHAW, M.D..

SANDER AND OTHERS ON EPILEPSY.—A discussion took place at a meeting of the Berlin Medico-Psychological Association last year 'On the Forensic Significance of Epilepsy' (*Berliner Klinische Wochenschrift*, Oct. 6, 1873). Herr Sander spoke of epileptic attacks, which might easily be overlooked or not recognised as epileptic, and of the extent to which the presence of such attacks would become a medico-legal question; also, how far the mental condition of an epileptic in whom no insanity in the ordinary sense was discoverable, might be abnormal, and a matter of legal doubt. Herr Skrzeczka said that, whereas we assumed in the case of ordinary mortals that they committed their acts with consciousness, this presumption did not hold good in the case of epileptics; the very fact that a man is an epileptic demands a great degree of caution in judging of any act of an extraordinary nature. In judging of the various symptoms we must give great weight to anamnesia, and must ask how far such symptoms as these belong to epilepsy, viz., night terrors, waking covered with sweat after fearful visions, and perfect unconsciousness thereof in the morning. Such symptoms would be of the gravest importance, if on further investigation we find vertigo and other marks of epilepsy. As regards loss of consciousness, he mentioned a case where attacks of complete unconsciousness alternated with others where it was incomplete. An old lady suffered from a dream-like state, which seemed as if the world was covered with a veil and everything changed. At times, instead of this, there was complete loss of consciousness, and no recollection on waking of what had passed. Herr

Jastrowitz remarked that there is not always loss of consciousness where there is an epileptic attack, but in such cases there would not be much legal difficulty. The difficulty arises when the criminal act is the first sign of epilepsy, and there are only slight indications of the disorder. Herr Westphal thought that the existence or non-existence of consciousness was the main point to be discussed. We have no objective test of loss of consciousness; we have only the word of the patient. He narrated the case of a young man, whose attacks were feigned. This was revealed by talking during an attack of certain symptoms, which in a subsequent one he simulated. Though patients say they were unconscious, they often know to some extent what has happened. Neither can we trust to the reaction of the pupils, which sometimes act even when we find convulsions and loss of consciousness.

Herr Sander, in reply, said that many topics had been broached which must be discussed at another time. It was important to consider at first the epileptic attack proper, and therefore he left to future consideration the condition of a protracted loss of consciousness in which many things might be done. It is a question, however, whether we are to consider those attacks in which consciousness is more or less retained, as epileptic, or are to exclude them from this category. Romberg's test that epileptic and hysterical attacks are to be distinguished by the presence or absence of consciousness is correct in the majority of cases; but if we observe a great number we find in some there is no loss of consciousness, and yet they are unquestionably of an epileptic nature, and there are cases with loss of consciousness which in every other respect are of an hysterical character. Then there are attacks preceded by an aura in which consciousness is not lost; and others where the aura only exists, and which do not go on to loss of consciousness. Are we to consider these as non-epileptic because consciousness is preserved? Proof of consciousness is not to be derived from the feeling of pain, for movements caused in this way may be reflex; we can only tell that the patient is conscious if he be aware of what has happened during the attack. As scarcely any patient has an interest in feigning consciousness, we may accept a statement of what has happened during the attack as a proof that he was conscious. And many remember more or less what has gone on during the whole or a part of the attack. Dr. Meyer's objection that an epileptic attack cannot consist of insensibility without motor affection he does not consider valid, for in some patients we find at one time insensibility only, at another attacks with characteristic convulsions; or the attacks with insensibility may precede those with convulsions. The influence exercised upon the mental faculties, and the gradually increasing mental weakness often shows that these fainting attacks are truly epileptic.

G. FIELDING BLANDFORD, M.D.

SKAE ON INSANITY CURED BY TREPHINING.—Dr. C. Holland Skae reports (*Journal of Mental Science*, Jan. 1874) the case of a coal-miner who, four years previously to admission into the Ayr Asylum, had been struck on the head by a mass of falling coal, causing fracture of the skull about three inches above the left extremity of the left eyelid. He lay insensible for four days, and then recovered and resumed work in a few weeks.

Not many weeks later, his wife and friends noticed

an alteration in his habits and nature. Instead of being cheerful and sociable, and kind to wife and children, he became irritable and moody. At home he would sit moping over the fire, and act bearishly and roughly to those about him. Then he became excited, used threatening and violent language, and conducted himself in this way to all. Eventually he became acutely maniacal, and attempted his wife's life and also his own. He had a succession of epileptic fits before being brought to the asylum. On admission he was sulky and taciturn, and had a morose and ill-natured expression. He had a well marked depression with an ugly cicatrix about three inches above the left extremity of the left eyelid, which latter slightly dropped. He was two months in the house before the operation, and had slightly improved, that is, he conversed to some extent with certain persons, but would not join in work or amusements, was suspicious, and had delusions regarding the conduct of his wife and friends. Trephining was performed in 1870 by his former medical attendant, Dr. Clarke Wilson, of Ayr, and a piece of depressed bone removed. After a week or two in bed, the patient was moving about again, and gradual improvement took place in his conduct: he soon became a different person, and his affection for his wife returned in full force. He became cheerful and active, and was soon discharged sane. He has ever since supported his family, and has visited the asylum regularly at intervals of six months, apparently quite well.

NEWINGTON ON SYPHILITIC INSANITY.—In the *Journal of Mental Science* for January, 1874, are reported four cases of syphilitic insanity, so called; and upon the subject Dr. Hayes Newington makes some observations. He finds in various works the following relations between syphilis and insanity. 1. Acute mental disease may occur coincidently with or even preceding and following the eruptive stage. This is rare, and seems to require great brain-vulnerability for its production. 2. As a companion to the tertiary stage, may occur a condition found with other forms of meningitis, to be followed often by dementia. Dementia also occurs sometimes without appreciable intervening changes, but then it would be impossible to say that syphilis unaided had been the cause. 3. We meet with cases caused, not so much by a specific brain-destruction, as by the sequelæ of a syphiloma. This condition might be well described as syphilomatous insanity. The name would, at all events, tie one down to a precise diagnosis, and at the same time afford pathological information to a reader of statistical tables of insanity. 4. We again find syphilis existing in relation to melancholia; not a specific one, but on the other hand, one that requires careful investigation before it is admitted in any given instance. Of course we reject mere syphilophobia without any manifestation of the disease. But we admit the power of corporeal diseases to determine at least an attack of melancholia; therefore it is reasonable to include syphilis as an agent in producing this form of disease. Dr. Newington's case, and also the two reported by Dr. Batty Tuke, are examples of insanity, complicated with epilepsy, and in all three there was some amount of paralysis; in the first there was ptosis of one eyelid, in the other two some degree of hemiplegia. Probably all these would be placed by Dr. Newington under his third head, and be considered as examples of syphilomatous insanity. The fourth case, reported by Dr. Francis Cadell, was that of a gentleman aged forty-eight, in

whom acute mania came on eight months after he had contracted a chancre. He recovered in three months, and three months later lapsed into melancholia, from which he recovered in about two years.

G. FIELDING BLANDFORD, M.D.

RZERUCHA ON MANIA WITH INTERCURRENT FURY.—In the *Medico-Chirurg. Centralblatt* for Jan. 2, 1874, is the history, by Rzerucha, of a person nineteen years old, insane, whose history was as follows. He had never suffered from fits; indeed, up to his present illness he had been quite well. His grandmother had been insane, but in what way was doubtful, and her husband was one day taken dead out of a brook. The patient's mother was of very limited intelligence, and simple in her manner. A year before, the first, but very transitory, traces of mental disturbance appeared. Since then, he had followed his business until four days before the medical visit. Ten years previously he had been bitten by a dog. He was temperate, of middle size and slender build. The pulse was seventy in a minute, full. The pupils were normal. Sleep was almost entirely absent, or, at the most, of half-an-hour's duration and much troubled by dreams. He complained of difficulty of swallowing and of scraping sensations in the neck, and of hearing voices persecuting him; and though answering questions fairly well, yet there was a want of coherence in his thoughts, and he was easily diverted from the conversation that he most desired to sustain, for he thought that all wished to harm him, to betray or destroy him, whence he became violent, and threatened to injure himself or others. He could recognise pieces of money, and count them and give the names of the days of week.

The question of diagnosis was between hydrophobia, delirium tremens, and mania; but the long period (ten years) that had elapsed since the bite, together with the facts that the dog was quite healthy, and that there was no scar, rendered the first opinion improbable; whilst the difficulty of swallowing and sensation of tickling in the neck were probably untrue, for he swallowed large quantities of water readily. The absence of the peculiar hallucinations of delirium tremens, and the fact that he was always abstemious, reduced the diagnosis to mania with intercurrent fury. He was treated with a grain and a half of tartar emetic daily, and twenty grains of chloral hydrate at night. Soon the doses of these were increased, but the tartar emetic made him vomit, and the chloral seems to have been most useful by promoting sleep. After thirteen days' treatment he recovered, but only for a short time, for in fourteen days he was again taken ill, and this time he was sent to the asylum at Prague. Dr. Rzerucha gives the fullest adhesion to the virtues of chloral hydrate.

T. C. SHAW, M.D.

VON BISCHOFF ON A CASE OF MICROCEPHALISM.—Dr. T. L. W. Von Bischoff gives an anatomical description of a microcephalic girl, in the *Abhandlungen der Königl. Bayerischen Academie der Wissenschaften*, 2nd series, vol. xi. part 2. Helene Becker was born June 22, 1864, at Offenbach, of healthy well-formed parents. Her mother had previously borne two healthy children, yet living. Subsequently she bore three, of whom two also are living, and are well formed. The last child, born in September, 1870, is living, microcephalic, and on the whole like Helene, but shows more intelligence. The mother appears to have

suffered derangement of her health during these two pregnancies.

The child Helene died on February 20, 1872, at the age of eight years. She had manifested most extreme mental deficiency, and had not progressed in any degree mentally. Pleasure and pain, joy and grief, were properly the only external signs of psychical energy observable in her. Coaxing or scolding made equally small impression. She recognised no difference between the persons about her, whether relations or strangers. She knew her own name when spoken, but took no notice of the difference when called by any other name. She had no trace of memory. Not one word could she utter, although she could make a loud cry, giving forth two vowel sounds, if pleased; on the other hand, when in pain or angered, she would put forth a piercing cry. The sight of the left eye only was perfect, and she could distinguish bright glittering colours, especially red. The right eye was blind. Hearing was perfect on both sides, but loud or shrill tones were unpleasant to her. The sense of smell seemed to be unimpaired. Cutaneous sensibility was manifested on touching, pricking, &c. She exhibited no desire for food, and required constantly to be fed; she preferred seasoned food, and drank wine more eagerly than water or milk. The power of maintaining her bodily temperature was but slight; her hands and feet were always blue and cold. The heart's action was feeble, the pulse, usually 132, sank to 116, after prolonged rest. Digestion was good. The evacuations were passed without notice by herself. There existed a morbid excitability of the genitals; her hands were constantly on those parts, and if hindered she manifested not the slightest degree of shame, but resumed the act as soon as her hands were free. She could neither walk nor stand, was kept constantly on a bed or in a chair. She was extremely restless, and her limbs were constantly in purposeless movement. She would seize brightly coloured objects, but she had no special care for the dolls and toys with which her sister played. She slept very little, and during slumber, her limbs were jerked about. Her health was bad; she suffered much from catarrhal affections and ophthalmia. She was of a rickety constitution, and died at last of disease of the lungs.

The body and limbs were considerably distorted and wasted. The length of the body was about 30·8 inches; its weight was about 17 $\frac{3}{4}$ pounds avoirdupois. The weight of the brain, with its pia mater and arachnoid freshly taken from the cranium, was 219 grammes (about 7 $\frac{3}{4}$ ounces avoirdupois). After having been kept a day in solution of chloride of zinc, the membranes removed, and then transferred for fourteen days into spirits, it lost half its weight. Dr. Bischoff remarks that this, for its age, is the lightest brain on record, with the exception of one described by Dr. Julius Sander (Griesinger's *Archiv für Psychiatrie*, 1867.) The cerebellum, pons, corpora quadrigemina, and medulla oblongata weighed only 27 grammes, i.e. about one-fourth of the entire brain. The aspect of the brain was healthy, and resembled in configuration that of the ape tribe. The size and general characteristics of cerebral lobes, convolutions, and fissures were closely assimilated to those of the cynocephalus. The frontal lobes were prolonged forwards to a beak-like point. The posterior lobes of the brain were so slightly developed, that the cerebellum was uncovered behind. The temporal lobes, more particularly anteriorly, were

fully developed. The cerebellum, pons, and medulla oblongata were all large, and appeared normal.

The details of the deviations from the normal conditions of the convolutions and fissures of the brain are given by the author, and illustrated by engravings.

Dr. Bischoff accompanies his description of this microcephalic brain, with a survey of the literature of the class of malformations to which it belongs, and considers that by the complete history of such an instance he has supplied an existing deficiency in pathological science. [We would, however, point out that one of the cases to which he refers, viz., that recorded by Mr. Gore (*Anthropological Review*, vol. i. p. 168, 1863), has been subsequently described by Mr. John Marshall, in a paper read before the Royal Society, June 28, 1863 (*Philosophical Transactions*, 1864).—*Rep.*]

A microscopical examination of the brain was made by Professor Betz. The corpora pyramidalia of the medulla oblongata were smaller than usual, and the corpora olivaria seemed to have been arrested in their development, as had also the central ganglia of the brain. The cortical substance contained only large cells covered with a thick layer of connective tissue. The gray substance of the convolutions of the hemispheres showed a normal condition of the cells, neuroglia, and nerve-fibres, as did also the intimate structure of the cerebellum.

The cranium of Helene Becker is one of the smallest that, for the age of the child, has been observed. Peculiarities were observed in the bones of the skull, and are recorded by Dr. Bischoff. The muscular system was much wasted. The digestive organs and alimentary canal showed very slight deviation from their normal characters.

In the structure of the heart no deviation was observable. The large vessels rose from the aorta in the same manner as in anthropoid apes. The genital and urinary organs presented no deviation from the normal type. The ovaries and uterus were as little developed as in a new-born child.

W. B. KESTEVEN.

HUN ON MORBID APPEARANCES IN THE INSANE. Dr. Hun, the pathologist of the New York Asylum (*Report of the New York State Lunatic Asylum*), writes, that in every case examined there was some considerable disease of the brain and its membranes. The well-known connection between tuberculosis and insanity is well illustrated by the fact that, out of twenty-four cases, fourteen presented evidence of tubercular disease of the lungs. The peculiar deflection of the transverse colon towards the pubes, frequently mentioned, was observed in seven of the twenty-four. Among the abnormal conditions revealed by the microscope, were a granular fatty deposit in the enlarged perivascular sheath of the smaller vessels of the brain, a fatty degeneration of the nerve-cells, an increased proliferation of the connective tissue, small effusions of blood from rupture of capillaries, microscopic miliary aneurisms (as described by Charcot), and many other lesions not yet classified. In the brain of a female who died during an attack of subacute mania was observed, for the first time, a peculiar lesion of the brain and spinal cord, which afterwards was met with in a number of cases of insanity of various forms. Sections of the tissue, previously hardened in absolute alcohol, and coloured with carmine, were rendered

transparent with benzole and mounted in balsam. Examined by transmitted light, they could be seen with the naked eye to be studded with small white spots, which were very numerous and of variable size. Under the microscope, these spots presented a granular appearance, and many contained a number of elongated crystalline bodies. They did not imbibe the carmine solution to the same extent as the surrounding healthy tissue, and were of a pale greenish colour. Their edges were not well defined, but the deposit seemed gradually to merge into the normal brain-substance. They were circular or oval in form, and varied in size from one-twentieth to less than one-fivehundredth of an inch in diameter. In some instances the nerve-fibres seemed to pass through them, but as a general rule they seemed to be destroyed. These bodies occupied the white substance of the brain, none being found in the gray matter of the convolutions. They were observed in three females and four males. Last year the attention of Dr. Hun was called to another form of deposit in the brain-tissue, which differed from the preceding in that the spots were smaller and their outline more distinctly defined. These deposits were very dense and white; they did not imbibe the colour from a carmine solution, and contained none of the crystalline bodies observed in the first variety. They appeared to be surrounded by a capsule of condensed connective tissue, and none of them were traversed by nerve-fibres, the latter being pushed to one side. They could be easily detached from the healthy tissue by teasing out the specimen with a needle; and in one section, accidentally torn, the morbid deposits could be seen protruding from the torn edge in the form of rounded projections. This second form of deposit was found in five males and one female. G. FIELDING BLANDFORD, M.D.

REVIEWS.

Mineral Springs of North America, how to Reach and how to Use Them. By J. J. MOORMAN, M.D. Philadelphia. 1873.

Dr. Moorman tells us that he has practised for thirty-five years at the White Sulphur Wells. He is therefore able to speak of them, with all the weight due to lengthened experience of them; and when he gives a survey of all the other known springs in America in his compact volume, he discusses them also in a practical way. The chief defect of the book is, not that the springs are classed geographically, and therefore without much reference to their nature; but that there is an absence of generalisation, and that there are no comparative tables of the constituents of different wells. It is hard to find out from the book without some search, to which class particular springs belong. We are often tempted by allusions to beautiful mountain scenery, but in only two or three instances is the actual height above the sea of any bath given. With some difficulty, indeed, we have gathered, that Montvale springs are 1,400 feet above the sea, the Yellow Sulphur 2,000 feet, and the wonderfully copious sources of very hot water, supplied by the Hot Springs of Arkansas, are delightfully situated in a valley 2,100 feet above the sea. The analysis of many of the waters is old, and is almost always given in the old-fashioned calculation by gallons, so that it is difficult to use such analyses as are given, for purposes of comparison.

We are surprised to find that there is not a single reference to any French or German work on balneology; and it is probably in consequence of an imperfect acquaintance with European waters, that different baths are often jumbled together in an odd fashion. For instance, we are told that 'some of the ingredients of American aluminous sulphated chalybeates are to be found in the most distinguished of the English and German waters, particularly in those of Tunbridge, Harrogate, Leamington, and Aix-la-Chapelle, as well as in the waters of the famous Spa in Belgium, in those of Passy, and in the celebrated springs of Bagnères in Garonne.' Then, boasting of the amount of mineral constituents, although he elsewhere repeatedly remarks, that springs are not to be estimated simply by their mineral contents, the author says of a certain chloride of sodium spring, 'that it is about 10 per cent. stronger than the celebrated Congress spring, while it is four times that of Baden Baden in Austria (!), twice that of Vichy in France, nearly three times greater than the renowned Selzer of Germany, and five times greater than that of Aix-la-Chapelle in Prussia.'

Dr. Moorman has felt a delicacy in expressing his opinion of the arrangements, or, as he calls them, the improvements of different springs. In consequence of this, we can learn little or nothing of the drinking, the bathing, or the douching arrangements. Apparently there are no inhaling rooms in America. We confess that for strangers, it would have been more satisfactory, if he had maintained less reserve. In almost a solitary instance he ventures to praise the improvements at Beersheba, where, he tells us, 'the society is always select, elegant, and cultivated,' but says little more. Notwithstanding such drawbacks, Dr. Moorman's book has brought together a great deal of scattered information, from which we shall endeavour to glean a few general notions.

As regards their geography, the states of Virginia, West Virginia, and of New York, produce far the greatest number, as well as the most important, of the springs of North America. They occur in great numbers on the western and eastern slopes of the Alleghany range, and also in the Shenandoah Valley, between the Apalachian and the Blue Ridge mountains. There are many springs in other parts, some of the most notable of which, especially thermal ones, are in California, or near the great Salt Lake; and the hottest of all, and boiling springs, are the Hot springs, Pyramid Lake, Nevada. The few springs in Canada, of which we have authentic accounts, are not very important. The Varennes saline and chalybeate springs were formerly popular.

Next as to particular kinds of water, thermal springs, and they are nearly indifferent ones, are represented by the Berkeley and Sweet springs, two of the baths which have been used for more than a century. Their temperature is low, and nearly identical, about 72° to 74°. A little warmer are the Healing Springs, 86°, Buncombe, 94° to 104°, Warm Springs, 98°, and the Washita hot springs of Arkansas, as high as 140°. The amount of solid constituents in these waters is small. They are used very much in the same cases, as similar waters in Europe. Neuralgia, rheumatism, gout, also uterine affections, are among the principal diseases treated. The sweet springs resemble closely in composition the old Bristol hot wells, now removed to widen the channel of the Avon, and have been used with advantage in incipient phthisis, in chronic bronchitis, and in dys-

pepsia, very much as their prototype was employed eighty years ago.

The sulphur waters are extremely numerous, especially in Virginia, and there are a good many in New York. Of those in popular use, none can be called thermal. The chief are the White Sulphur, fully treated of by Dr. Moorman. Besides them, there are the Salt Sulphur, and the Red Sulphur, and other springs in Virginia, and the Avon waters in New York. All these contain sulphuretted hydrogen in greater or smaller quantities, often in very large ones, but they also contain sulphate of lime and magnesia; indeed, so little importance is attached to the gas present, that therapeutically, the sulphur wells are treated in this work as equivalent to saline springs, and we shall mention some of the latter before coming to the medical action of both.

In America they have no regular saline springs, that is, wells containing any considerable amount of sulphate of magnesia, or of sulphate of soda. Salts of lime usually predominate in what are called saline. As specimens of this very abundant class, one of the strongest, the Alleghany springs, may be mentioned, and one of the weakest, Gettysburg. The last has grown into sudden repute, since the battle which occurred at that place; but it is really an indifferent water, from which one would not expect much, as it seems to be only of ordinary temperature.

Dr. Moorman regards the action of most of these springs, especially of the White Sulphur, which he knows best, as profoundly alterative, altering deranged organs, as he expresses it. He is entirely in favour of the continued use of small doses, and dislikes irritative action or bath crises. He considers their operation to be analogous to that of the alterative action of mercury; they sometimes cause salivation, and are of the greatest service in cases of metallic poisoning. It is sometimes expedient to lower the phlogistic diathesis, before commencing the use of these waters, especially when they contain considerable quantities of gas. Gas often proves too stimulating, and in many cases it is better to let the gas escape, before the water is used. Dr. Moorman considers this of less importance, because he believes that there is a secondary generation of gas in the intestines, when the water has been drunk, deprived of it. It is worthy of note, that the Red Sulphur Springs enjoy great repute in pulmonary cases. Perhaps the most important practical hint to be got from the saline waters, is the great success with which it is affirmed that they are used against chronic diarrhoeas acquired in the South. The Montvale springs in Tennessee, containing lime and some iron, have a great reputation in such affections. Dr. Moorman thinks the use of the White Sulphur waters a very important aid in curing both chronic inebriety and opium-eating.

Coming next to chloride of sodium, we find New York State amply supplied with excellent waters, well stocked with salt, iron, and carbonic acid. The waters of Saratoga and Ballston can hold their own with Homburg and Kissingen. These wells have long been known, and may be said to enjoy a European reputation. There is a whole series of springs at Saratoga, including High Rock, with its curious conical enclosure of calcareous tufa, and the Empire Spring, with a considerable amount of iodine; and there are six principal wells of the Ballston group. The indications for the use of such waters are very wide; practically, perhaps, they are used most for

dyspepsia, and they are especially efficacious, where there is congestion of the abdominal organs.

With chalybeates, and alumino-chalybeates still more, America is well supplied. Some such are the Red Sweet Springs, rather weak, the Rockbridge Alum, stronger, also the Beersheba and Buffalo springs. Bedford Springs, in Pennsylvania, and Schooley Mountain Spring, in New Jersey, are, owing to their height, favourite summer resorts. There must be abundance of pure chalybeates in America, though we are not told much about them; but many of the popular steel springs are strongly impregnated with alum. They must, therefore, be used with care, in small quantities, and usually diluted. Such ones have never been very popular in Europe.

There are a great many springs that go in America by the name of acidulous, not, as in Europe, from affording an abundant supply of carbonic acid, but as containing, like some Italian springs, considerable quantities of sulphuric acid. Some of the chief of these, as the Oak Orchard Springs, are in New York. The strongest is the Tuscarora acid spring in Canada. Such waters are used commonly, in small quantities, as tonics and astringents. We know little of them in Europe, but they should be borne better by the stomach than the alumino-chalybeates.

We have already mentioned the absence of strong saline or purgative waters.* There seems also to be an entire want of alkaline waters, except in some distant regions, and of wells containing soda, the St. Louis Magnetic Spring being almost the sole exception to this. No waters appear to have been noticed as being arsenical, nor do most salt springs contain much iodine, or more than traces of lithia.

Dr. Moorman talks, with very proper reserve, of an American water that has of late years obtained a spurious popularity in cancer, the Missisquoi Spring. We have had occasion to know the details of several cases, in which it was employed in this country under competent surgical advice, and, it need scarcely be said, to no purpose in each instance. For some time the water appeared to have a certain amount of soothing power, which was probably the result, on the patient's mind, of the trial of a new and wonderful remedy. There would seem to be no quantitative analysis of it. But it is apparently an extremely weak saline spring, and does not profess to contain iodine. The proprietors of the spring themselves tell us, that 'its correct analysis is withheld for many reasons.'

In taking leave of Dr. Moorman, we would say, that we have gathered from his sensible volume a great deal of information, probably as new to the readers of this notice as to the reviewer.

J. MACPHERSON, M.D.

On Marienbad Spa and the Diseases curable by its Waters and Baths. By A. V. JAGIELSKI, M.D. Berlin. 12mo. pp. 185. London: Trübner & Co.

Dr. Jagielski writes his book 'to fill the existing vacancy in modern English balneological literature.' If he mean by this, that there is no separate English monograph on Marienbad, no doubt he is correct; and his remark would be applicable to most Continental baths. Nevertheless, Marienbad attracted the attention of English balneologists long ago, and we have full and sufficient accounts of it in the older

* The Saloon Spring at Harrodsburg, containing 28 grains of sulphate of magnesia in the pint, is one of the strongest.

writings of Granville, Johnson, and Edwin Lee, and we believe that it has been noticed in all more recent balneological works. Still Marienbad is so delightful a spot, and so efficacious are its waters, that we are glad to get this very complete account of the place. In it are given the results of the practice of the resident physicians; indeed, a great variety of subjects is handled, including the theory of the operation of mineral waters, and the general principles of hygiene, which are treated of at rather disproportionate length for a mere local handbook. As we observe no references to the personal experience of the author, we infer that his work is mainly a digest of the writings of others.

Like most books of the class, it is written somewhat exclusively in favour of the waters of which it recommends the use, both on the spot and at a distance; and we think we see something of this exclusive spirit in the cursory way in which the very admirable chalybeate waters of the rising and neighbouring spring of Königswarth are mentioned. However, Marienbad, the cold Carlsbad as it has been called, can afford well to stand on its own merits, being situated at a height of 2,000 feet among beautifully wooded hills, and containing so great a variety of springs. These include strong alkalo-salines, weak alkalo-salines, alkaline chalybeates and earthy chalybeates, for drinking; and for bathing, steel baths, mud baths, pine-leaf baths, for those who care for them, baths of carbonic acid gas, which last stand in need of improvement in their arrangements.

We can on the whole congratulate Dr. Jagielski on the way in which he has executed his work, and also generally on his English; although he must have had a very imperfect notion of the meaning of the word ravine, when he commenced his book with an announcement, very startling to any one that has visited Marienbad, that it 'lies in a lovely balsamic ravine.'

J. MACPHERSON, M.D.

MISCELLANY.

THE COMMUNAL HOSPITAL IN COPENHAGEN.—The report of this hospital for 1872 shows that the number of patients admitted during the year was 6,781, and the average daily number in hospital 619; while in 1871 the numbers were 7,655 and 693. The reduction is attributed in part to the institution of a small-pox hospital. The average time during which the patients remained in hospital was 30½ days. State Councillor Rörbye had determined on presenting to the hospital library his collection of medical works, and a portion had been received. A widow lady named Lund had left the hospital a sum of money, the yearly interest of which (320 rix-dollars, equal to about 37*l.* 6*s.* 8*d.*), was to be given in prizes to the nurses. There were 103 cases of small-pox, of which 18 died; and 77 cases of typhus fever, with 9 deaths. Five cases of pyæmia, of which four were fatal, occurred in one of the divisions of the hospital. Of erysipelas, there were 141 cases, of which all recovered except 9. The small-pox hospital, which was opened on November 4, 1871, received in 1872 999 patients, making, with 34 under treatment on January 1, 1,033, of whom 896 recovered, 113 died, and 34 remained under treatment on December 31. Another small-pox hospital was opened in the women's workhouse on January 14, and was open till October 22, with the exception of an interval from June 26 to July 5. In it 855 cases of variola were received, of which 99 died. There were in both institutions more cases of the hæmorrhagic form of the disease, than had been known in Copenhagen since the introduction of vaccination.

MEDICAL MUTUAL AID SOCIETY OF LOMBARDY.—The report of the *Società di Mutuo Soccorso pei Medici e Chirurghi di Lombardia* for 1873 shows that during the year 67 grants were made, 15 to members of the society, 49 to widows, and 3 to orphans. The sum distributed amounted to 9,600 *lire* (384*l.*). The total income for the year was 10,874 *lire*, of which only 2,680 *lire* was derived from annual subscriptions, the remainder being from funded property. The report appeals urgently to the profession in Lombardy for increased support.

THE forthcoming celebrations of Professor Rokitsansky's seventieth birthday appears to be exciting much interest. Several of the Universities, as Innsbruck, Gratz, and Prague, will be represented by deputations on the occasion.

TRICHINOSIS.—The *Berliner Klinische Wochenschrift* of February 9, says that cases of trichinous disease lately occurred in one of the districts of the city; but it was hoped that measures would be at once adopted with sufficient energy to prevent the spread of the disease. A number of cases were reported also from Potsdam. The occurrence of this disease, our contemporary says, gives an unfavourable idea of the condition of sanitary matters in Prussia; there is scarcely any disease of which the etiology is better understood, or which can be more certainly avoided than trichinosis.

PUBLIC SCHOOLS.—PRECAUTIONS AGAINST INFECTIOUS DISEASES.—Dr. Whitmore, the medical officer of Marylebone, has, in consequence of the prevailing and fatal epidemic of measles, sent a circular not only to the managers of every school in his district, but to every member of the London School Board, in which he states that measles is to a considerable extent disseminated by the free intercourse which takes place amongst children of the poorer classes in parochial and other public schools. He suggests that all school managers should take the trouble to ascertain whether children attending schools come from houses where measles, &c., exist, and prohibit further attendance until such houses are free from infection; also, that any room or cupboard used for children's hats, caps, bonnets, cloaks, &c., should be constantly disinfected by the free use of chloride of lime or carbolic acid.

DR. HOFFMANN, senior assistant in Professor Ferrieh's Clinic in Berlin, has been appointed Professor of Clinical Medicine in the University of Dorpat.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 17*s.* 4*d.*; free by post, 19*s.* 6*d.*

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19*s.* 6*d.* Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, FEBRUARY 25, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BRUNTON AND FAYRER ON THE ACTION OF SNAKE-POISON.*

A paper by Dr. Lauder Brunton and Dr. Fayrer, on the physiological action of the poison of *Naia tripudians* and other Indian venomous snakes, was read before the Royal Society on January 22. The result of the authors' investigations was to show that the poison of the cobra is similar in its action to that of Ophiophagus, Bungarus, and other Colubrine snakes, whilst that of Daboia is similar to the virus of Echis, the Trimeresuri, and other viperine snakes; the chief difference between them being the greater tendency in the viperine poison to cause hæmorrhage or more severe local symptoms. The blood of animals killed by the viperine snakes generally remains fluid after death, whilst that of animals killed by colubrine snakes form a firm coagulum.

The conditions caused by the action of the poison are illustrated by the symptoms manifested by man and the lower animals. The Cobra, Ophiophagus, Hydrophidæ, and Bungarus are all very deadly. The Viperine Daboia and Echis are scarcely less so; whilst the Indian Crotalidæ, such as the Trimeresuri, are much less so. A series of experiments was detailed, illustrating the physiological action of the virus on the nervous system, the muscles, the blood, the respiration, the circulation, and the functions of excretion, and also the mode in which death is produced.

Death may occur in several ways. 1. It may be due to arrest of the respiration by paralysis of the muscular apparatus, by which that function is carried on. 2. It may arise from rapid arrest of the heart's action, in cases where the poison has found direct entry by a vein, e.g. the jugular. In such, death is almost instantaneous, and the heart is found to have ceased to beat when in systole. The physiological import of this is very interesting and important, and it was demonstrated by Dr. Brunton, who explained its probable mode of action in certain ganglionic centres in the heart. 3. Death may be due to a combination of arrest of respiration and of the heart's action. 4. It may be due, where the quantity of poison is small, or its quality less active, to secondary causes of the nature of septicæmia, a purely pathological question not discussed.

The mode in which paralysis of respiration (the ordinary form of death) is induced, has been most thoroughly investigated.

The virus absorbed into the blood, either by inoculation into the areolar tissue, or by application to a mucous membrane, affects the cerebro-spinal

nerve-centres, the nerves and their peripheral distribution, more especially of the motor nerves. The sensory nerves are less and later affected, and the intelligence generally latest of all, and slightly. The complete loss of it, and the convulsions which precede death, are mainly caused by the circulation of venous blood, the result of the impeded respiration.

Muscular force and co-ordination are gradually lost; paralysis and asphyxia being the evidence. In ordinary cases, the heart goes on beating vigorously long after apparent death, and, with artificial respiration, its action may be kept up for many hours.

The investigations recorded were made with cobra and daboia poison, sent to England from Bengal in the dried state, a condition in which it resembles gum arabic, and its activity is great. The animals experimented on were dogs, cats, rabbits, guinea-pigs, fowls, pigeons, small birds, frogs. Its action on all these, and the mode in which functions and tissues are affected, were recorded in detail, as well as the extent to which the action of the poison is modified when introduced through different channels.

The authors of the paper stated that it had now been clearly shown that the poison acts when introduced into the stomach, or when applied to a mucous or serous membrane. The idea that it is only effective when injected directly into the blood, is erroneous. It is, no doubt, more certainly and rapidly fatal when it enters the blood direct. It may be eliminated by the excreting organs; and there is, therefore, reason to hope that life may be saved if it can be artificially sustained long enough to admit of complete elimination being accomplished, as in the case of curare poisoning; but from the more complex action of the cobra poison, this remains a subject of doubt. By artificial respiration the circulation has been maintained, both here and in India, by Dr. Ewart and Mr. Richards, for many hours; and in one case, after complete paralysis had occurred, symptoms of reaction and elimination were obtained; but no complete recovery has yet occurred. The doubt still remains whether the nervous system, that has sustained so much damage, is capable of ever resuming its functions, even though elimination be complete.

The so-called antidotes appear to be inert; all that have been submitted to trial, including the intravenous injection of ammonia, have failed to have any satisfactory effect. Artificial respiration has certainly prolonged life, and partial recovery has followed, but no life has actually been saved by it.

The microscopic appearances of the blood were described, but no very remarkable change was observed beyond crenation of the corpuscles or diminished aggregation into rouleaux. Chemical examination of the blood and its gases is still needed, and further analysis of the poison is desirable.

The activity of the poison is scarcely impaired by drying, excepting perhaps so far as regards its local action. Dilution with water, glycerine, liquor ammoniæ, and liquor potassæ, did not destroy its activity, nor did coagulation by boiling in the ordinary way. The boiling for half an hour under a temperature of 102° C. (215·6 Fahr.) seemed to destroy the activity of one specimen which was injected into a bird.

The poison acts on all life, on the lower and higher vertebrata, on the invertebrata, and even on vegetable life; for it retards, although it may not arrest, the germination of seeds. But it acts most vigorously on the warm-blooded animals.

The most remarkable fact connected with it is that

* 'On the Physiological Action of the Poison of *Naia tripudians* and other Indian Venomous Snakes,' II., by Drs. Brunton and Fayrer, Royal Society, Jan. 22.

it has little or no effect on poisonous snakes. They can neither poison themselves nor their congeners, or if at all, very slightly so; whilst the poison acts rapidly and fatally on innocent snakes, lizards, fish, and mollusca.

With reference to the means of preventing death, those that mechanically prevent the entry of the poison into the circulation, such as of the ligature, excision, or cautery are the most reliable, but they are only so when applied immediately.

No means that offer any hope of benefit should be neglected, and it is possible that stimulants such as alcohol and ammonia may be useful; and in some cases, where the poisoning has been severe but not fatal, they may do good and even determine recovery where death would have otherwise resulted. The so-called antidotes, however, beyond any action of this kind that they may possess, are apparently quite inert.

Transfusion of blood was alluded to, and it was observed that the experiments hitherto proposed had not met with success, but that a more perfect way of accomplishing it might be more successful.

FRENCH AFFAIRS.

(From a Special Correspondent, Feb. 20.)

Our scientific bodies pursue their course of commendable activity here, and too much praise cannot be given to our younger and older savants, alike for their singular energy and earnestness, and for the renewed spirit with which they have thrown themselves into the scientific movement of the day, determined to conquer the Germans on this soil at least, and to place France, in truth, at the head of the scientific world, where we all loudly proclaim her to be, in the hope that others will believe us. I trust, notwithstanding the one or two angry remonstrances forwarded to you, and which you were good enough to place in my hands, concerning my suggestions of a few spots in the sun in my last letter, that you will allow me to pursue what I am persuaded is a healthy course, in reviewing the little excesses and defects of my learned and self-satisfied countrymen, while I note their progress.

One of the first sittings of the Académie de Médecine this year (Jan. 20) was occupied by a discussion, which was characteristic of the extraordinary ignorance or egotism, whichever it may be, on which I have before commented, which seems to compel my countrymen either altogether to ignore what is done abroad, or to mention it only as copied from or inferior to French work. In the *British Medical Journal* of last year, Dr. Ferrier, in a very ingenious and careful paper, started the hypothesis that the ammoniacal condition of urine in the bladder was frequently due to the introduction of septic germs by the catheter. He gave examples as well as arguments, and made the sensible suggestion that the sound should always be plunged into boiling water, or treated with carbolic oil, before or after use. M. Pasteur has presented the same theory to the Academy of Medicine, and it has been solemnly discussed at great length as a startling novelty by all our surgical and chemical luminaries. The discussion is quite worth reading, for the question is unresolved, and it was treated with great ingenuity, and even eloquence, by various speakers, including the 'flower of the two academies,' and M. N. Pasteur and M. Dumas, 'the two great masters of contempo-

rary chemistry' (*L'Union Médicale*). Nevertheless, the result was *nil*. Not even an allusion to Dr. Ferrier's practical suggestion of using an antiseptic solution (borax, carbolic acid, diluted oil of cloves, &c.) for the sound in cases of retention or of paralysis of the bladder. Is it not rather humiliating that, from simple ignorance of the most vulgar and accessible facts of foreign literature, 'the flower of our two academies, the Dumas, the Bouillaud, the Guéneau de Mussy, the Baily, the Ricord, &c.,' should be occupied for hours in grand debate on a stale little observation which was a year since relegated to history in a weekly paper issued by thousands broadcast over England, America, and the continent?

I send you a little 'summary of the progress of medicine,' by M. Garnier, which shows you what is considered 'patriotic.' In its exquisite simplicity of unvarnished ignorance and sublimely conscious egotism, it is, I imagine, unmatchable out of these latitudes. In the therapeutic summary there is not a word of croton, chloral hydrate, of apomorphine, of Harley's researches on the preparations of conium, of the researches on the injection of ergot, of Binz's and Baxter's researches on the action of quinine and alcohol. In medicine, not a word of Gull's and Johnson's researches on Bright's disease, of Sanderson's work on septicæmia, or in anatomy, of Klein's splendid investigations on the lymphatics, or Ferrier's, Hughlings Jackson's and Hitzig's revolutionary studies of the anatomy and pathology of the brain. 'Enucleation,' we are certainly told, is a discovery of M. Letiévant, as if Professor Miner's process of ovariectomy by enucleation had not been practised and discussed for the last four years. And so on through the whole catalogue. It is really pitiable, and must give foreigners a far worse idea of the state of science among us than we really deserve.

I do most heartily wish that a copy of your periodical could be presented to every intelligent practitioner in this city, if only that they could see French, English, and German work placed side by side, to discover what sort of a figure we really cut. A great deal of excellent work is being done here, but it is so disfigured by these traits of ignorant egotism, as to confound the real workers in the ridicule justly incurred by these journalistic praters.

CURSCHMANN ON THE THEORY OF FATTY HEART.

Dr. H. Curschmann, of Berlin, makes (*Deutsches Archiv für Klin. Med.*) the following observations regarding a case of fatty heart which was under his care in February, 1870, at which time he was assistant-physician in one of the hospitals of Mayence. The patient was a man aged thirty-two, a waiter, and, during the course of the affection which terminated in his death, at various times came under treatment, both in the wards of the hospital and also as an out-patient. His first admission into the hospital was in February, 1870. His previous health, up to 1868, had always been good. His parents were both living, and in good health. From his fourteenth year he had been a waiter, and during the last five years he had been in various hotels along the Rhine, and had been compelled to labour very actively. He had not been addicted at any period of his life to

* Translated, by Dr. W. H. Ashbridge, in *Philadelphia Medical Times*, January 17, 1874.

the excessive use of spirituous liquors, but, like all his class, had been very irregular in regard to his meals. He had never had syphilis, and had not indulged to excess in sexual intercourse. For two years he had noticed that his strength was failing, that he grew tired upon slight exertion, and suffered from shortness of breath from going up-stairs; but he still continued at his work until compelled by a severe cough, attributed by him to exposure to cold, and an increase of his above-mentioned sufferings, to seek the hospital. At the time of his admission, February 8, 1870, he complained of great weakness, frequent attacks of palpitation, and a constant shortness of breath, which at times increased in severity to a marked extent. His cough was frequent and troublesome, but accompanied with slight expectoration. He was compelled by his dyspnoea to maintain a half-sitting posture; his cheeks and lips were livid, a moderate amount of anasarca was present over his trunk and arms, while his lower extremities were markedly oedematous.

Auscultation of the lungs revealed a catarrh extending even to the finer bronchial tubes. The impulse of the heart could not be distinctly felt through the thoracic walls, and the area of percussion-dullness over that organ was much increased. The amount of urine secreted was small, and of high specific gravity. Under the use of the infusion of digitalis the symptoms ameliorated, the pulse became fuller, the anasarca diminished, and the symptoms of the catarrh of the lungs disappeared. The condition of the heart remained about the same; the impulse was weak and indistinct; the sound feeble, but no murmur could at any time be made out. The man was sufficiently well on the 28th of the month to be discharged, at his own earnest desire.

From the 2nd to the 17th of May he was in the hospital for treatment for a surgical affection, still suffering from shortness of breath and some palpitation, but had been able to work since his discharge, and did not complain in regard to his general health. An examination of the heart gave the same result as on previous occasions; the pulse was small and soft, and in a state of rest, scarcely 60.

On June 2 he again presented himself at the hospital, in a much worse condition than at the time of his previous admission. The symptoms were essentially the same as those of the previous attack, but more intense in character. The urine was scanty, and contained albumen; but after the use of digitalis the normal amount was secreted, and the albumen no longer appeared.

On July 4 the patient, much improved, was sent to his home in the Thuringian Forest, in the hope that he would there make more rapid progress towards convalescence.

On September 19 he came direct from his home to the hospital, and was again admitted, in a much worse condition than at his previous sojourn.

On October 5, in spite of repeated prohibition, he rose from his bed and went to the closet, where he suddenly fell dead.

At the necropsy the body was found oedematous, the skin livid. Upon opening the skull, the meninges were found filled with blood, the brain-substance strikingly light in hue and oedematous, and the ventricles somewhat enlarged and filled with a clear fluid.

The pericardial sac was not changed, and the contained fluid was of normal quantity and character. The circumference of the muscular substance of the

heart was quite double its normal size; the increase of the ventricles being proportional. The ventricles, as well as the auricles, were distended with fresh, dark blood. From the right ventricle the clots extended into the pulmonary artery, completely filling it and its larger branches. The walls of the cavities of the heart were thinned: the thickness of the wall of the left ventricle was one centimètre, that of the right half as much, and in some places but one-third of a centimetre. The muscular tissue in almost every portion was of a reddish-yellow colour, at some places quite yellow, very relaxed, and quite readily torn. These changes were more advanced in the right than in the left ventricle. The papillary muscles were long and thin, and when cut across showed yellow streaks. The valves of the heart were unchanged, of normal thickness, and capable of perfect closure. A microscopic examination showed that the muscles had undergone fatty degeneration, and that the striæ of the fibres were indistinct and had in some places vanished. The aorta and its larger branches, so far as examined, were unchanged. In the kidneys, beginning fatty degeneration was found.

The diagnosis of dilated heart with fatty degeneration was made at the time of the patient's first visit to the hospital. The fact of the dilatation was established by physical exploration; and the feeble pulse, and absence of impulse in conjunction with an organ increased in size, manifested a diminution of power. The question whether the diminished frequency of pulse is of pathognomonic value, as asserted by English authorities, is not discussed. No cause sufficient to account for the disease of the heart was discovered at the *post mortem* examination. No valvular affection of the heart was present, nor was there anything that could interfere with the course of either the greater or the lesser circulation. The supposition that was made during life, that the changes in the liver and kidneys were secondary in their character, was also supported by the autopsy. The first change that took place in the heart was an excentric hypertrophy, affecting both sides, followed by fatty degeneration and consecutive thinning of the muscular walls of the heart. This conclusion would have been warranted by the anatomical conditions found at the examination, even if accurate and continued observation during life had been wanting, for it would not be possible that so great a dilatation could take place in a heart of normal size. It would be possible only in a heart which was already increased in size and then underwent dilatation. In answering the query as to the cause of original excentric hypertrophy, it must be established, as it was by the autopsy, that there existed no perceptible mechanical cause. But, inasmuch as the microscopic examination revealed only a true muscular hypertrophy, and as this form of hypertrophy is, as yet, attributed only to mechanical causes (true hypertrophy from work, of Rindfleisch), something which is not demonstrable on the cadaver must have acted during life in a similar manner. This being premised, it is easy to bring forward as the origin of the excentric hypertrophy in his case a cause similar to that given in the observations of Traube—namely, severe and prolonged bodily exercise.

Upon the supposition that this was the cause of the hypertrophy, it is easy to explain the proportional involvement of both sides of the heart. The continued muscular effort of the left side, together with the reaction from the increased pressure of the column of

blood in the aorta and its branches, would furnish the cause of the increase of the arterial side of the heart; while upon the other side of the organ a like effect would result from the increased activity of the respiratory function, and consequent disturbance of the lesser circulation. After the hypertrophy had existed for some time, the patient meanwhile continuing to make the exertions to which his diseased state was due, fatty degeneration began. At the time of the first admission of the patient into the hospital, eight months before his death, his heart, although in a state of fatty degeneration, still had power enough to enable him to attend to his work until an intercurrent attack of bronchitis overcame the force of the diseased and weakened organ, and forced him to his bed. At the time of his death, the relaxed heart had still force enough to maintain the circulation while the patient remained quiet in the horizontal position; but when he stood up and attempted to walk, the task was too great for it: a sudden paralysis of its functions took place, and an acute œdema of the brain occurred, resulting in instant death.

MEDICINE.

THE DIAGNOSTIC LAWS OF THE LOCALISATION OF CHRONIC DISEASES OF THE NERVOUS SYSTEM. BY DR. M. BENEDIKT, PROFESSOR IN THE UNIVERSITY OF VIENNA.*

I will here first lay down the most important laws of localisation according to the aggregate and individual symptoms, and then pass on to the diffusion-law. The scales fell from my eyes when I examined, in the light of this law, many aggregates of symptoms, and criticised disputed questions; and I believe that I am not mistaken in saying that, since Bell's law, no principle has been so well adapted to render matters clear. The endeavours to refer all the symptoms in an aggregate (*Symptoms-complexe*) to one focus of disease (*Herderkrankung*) has led to the greatest confusion. I call to mind only the various localisations of foci of disease in tabes by Remak, the contest on localisation in aparetic dementia, in the lesser degrees of chorea, &c. The purport of the diffusion-law is this:—"When a combination of symptoms and aggregate of symptoms belonging to known and different localities is present, each must be localised in its recognised part."† Before this law can be clearly set forth in all its points, we must agree on the laws of localisation which may already be laid down in accordance with the present state of science. These special laws for individual aggregates of symptoms follow from the first general law of diagnosis, that the disease must be localised at the point of union of all the fibres whose irritation or paralysis produces the symptoms in question. This is the concentration-law of Bell and Rom-

berg. By this law I was enabled, even before a pathological anatomy of these diseases existed, to localise with accuracy progressive muscular atrophy, spinal paralysis in children, and progressive paralysis of the cerebral nerves.

The aggregate and individual symptoms, regarding the localisation of which we have certain evidence, are the following.

1. Paraplegia occurring simultaneously and symmetrically indicates disease of the anterior half of the spinal cord. Paraplegia of the legs usually indicates disease at the lumbar enlargement: paralysis of the arms, disease at the cervical enlargement of the cord.

The cerebral symptoms of paraplegia from disease of the spinal column usually indicate an affection of the roots of the nerves, and these are almost always at first unilateral: e.g., unilateral ischialgic pains in disease of the dorsal and lumbar vertebræ; intercostal neuralgia in disease of the dorsal vertebræ; cervicobrachial neuralgia in disease of the cervical vertebræ. Further, the unilateral development of progressive muscular atrophy, &c., may have its origin in disease of the lower cervical and upper dorsal vertebræ; the symptoms become bilateral at a later period, but it must not be forgotten that the spinal symptoms in spondylitis are not in proportion to the pressure of the distorted vertebræ, but may arise from myelitis.

2. Cerebral paraplegia is evidently composed of two separate hemiplegiæ.

3. Characteristic symptoms of tabes indicate disease of the posterior half of the spinal cord. Spinal contractions and spinal epilepsy are connected with disease or implication of the lateral columns.

4. Progressive muscular atrophy indicates disease of the grey substance of the spinal cord in the neighbourhood of the central canal, or in any case diffuse disease of the anterior roots; and the same is indicated by the supervention of muscular atrophy on an aggregate of spinal symptoms. I will discuss the symptoms of disease within the cord more at length in a special chapter. I will there endeavour to show that the modern doctrine that progressive muscular atrophy is a primary myositis is clinically untenable; and I hope also to prove that not the great motor cells, but other cells of the grey substance, must have an influence on nutrition.

5. Hemiplegia, with cross hemianæsthesia, indicates disease of one lateral half of the cord. From the analogy of hyperæsthesia after section of the sympathetic in the neck, it is beyond doubt, that hyperæsthesia of the same side in unilateral disease of the spinal cord arises from destruction and paralysis of the vaso-motor nerves.

6. Bilateral neuralgia, with wasting of the arms or legs, indicates disease of the posterior roots, and of their extension into the posterior columns, especially the inner radiating fibres (Charcot). (It is almost superfluous to point out that neuralgia of the limbs on the same side indicates an affection of the brain.)

7. Progressive paralysis of the cerebral nerves indicates more or less diffuse disease of the nuclei of these nerves, or diffuse disease of the peripheral nerves of these nuclei, principally from chronic basilar meningitis.

8. Paraplegia of the tongue (alalia) and of deglutition, indicate disease at the level of the hypoglossal and glossopharyngeal nuclei. This fact is especially important with regard to the localisation of disorder

* *Allgemeine Wiener Medizinische Zeitung*, nos. 1, 2, 3, 1874. From an *Introduction to the Pathology of the Nervous System and to Electro-Therapeutics*, now in the press.

† The author uses the terms diffusion-law (*Diffusions-gesetz*) and law of diffusion (*Gesetz der Diffusion*) in two different senses; the former in that indicated here, the latter as meaning the manner in which disease is diffused from one part to another, e.g., according to the manner in which the blood-vessels are distributed, &c.

of speech in mental disease; and, since I pointed it out in 1871, it has been established by Lubimoff. The facial paralysis, usually unequal on the two sides, occurring often along with complicated cerebral symptoms, is to be attributed to simultaneous disease of both nuclei of the facial nerves.

9. Hemiplegia, with cross facial or oculo-motor paralysis, indicates disease of the pyramidal fibres at the height of the nuclei, or at the points of exit of the nerves in question.

10. Hemiplegia, with hemianæsthesia on the same side, indicates disease of the fibres of the pyramids at the point in the medulla oblongata where the stimulation of the sensory fibres is completed, up to and including the radiation of the outermost bundle from the pes of the crus cerebri to the medullary masses of the hemispheres behind the lenticular ganglion. According to Türck's researches, however, it is a question whether the limitation of this region can be made so exactly as has been done by Meynert. Charcot, at least, holds to Türck's view.

11. Hemiplegia with incomplete paralysis of the facial nerve (the upper branches remaining free), indicates disease of the central motor ganglia of the brain. As I have seen complete paralysis of the facial nerve in cross paralysis of the oculo-motor and of the extremities, it is evident that the fibres for the upper facial branches separate from those of the lower branches and the pyramidal fibres, above the nucleus of the oculo-motor nerve, and radiate separately into the central ganglia. Further, electric investigation in cases of paralysis leads to different conclusions as to the localisation of the disease within the cranium. A fall of the electro-muscular contractility indicates that the disease is outside the central ganglia; if, on the contrary, it remain intact when the disease is of long duration, it indicates disease within the ganglia.

12. Hemiplegia with convulsions indicates disease to the central side of the central ganglia, in the fibres of the corona radiata, or in the hemisphere itself. Paralysis not preceded by convulsions arises from disease of the hemispheres.

13. Aphasia associatoria, *i.e.* disturbance of speech with complete or relative retention of the movability of the tongue, and of the power to attempt speech, indicates disease of the region of the claustrum, which, according to Betz, represents a ganglion of the hypoglossal nerve at its posterior part.

14. Hemiplegia with convulsions and aphasia associatoria indicates disease of the frontal lobes, near the convolutions of the island of Reil.

15. Hemiplegia with convulsions and bilateral neuro-retinitis denotes disease of the parts of the hemispheres above the optic thalami, and in any case above the corpora quadrigemina.

16. Cerebral convulsions without paralytic complications are to be referred to the posterior lobes.

17. Psychical symptoms always denote primary or secondary disease of the cerebral hemispheres or of the cortical substance. Motor and psychical disturbance and mania are especially to be localised in the anterior half of the brain; disturbance of the emotions in the posterior part (Schroeder van der Kolk). This is true only of purely psychical symptoms. Most of the symptoms of paralytic dementia are, as we shall presently see, to be localised elsewhere.

18. Statical vertigo (the drawing to one side) is a cerebellar symptom in the wider sense—*i.e.* of disease of the cerebellum and its extension into the cerebral peduncles.

19. Motor symptoms of irritation in diseases of the central nervous system are not self-evident indications of disturbance of the motor-nervous system, in Bell's sense, but are eventually connected with the co-operation of organs in juxtaposition (the posterior and lateral columns, the cerebellum in the most extended sense of the word, the cerebral hemispheres, &c.). Of tetanus, the special form of contraction and epilepsy, static and cerebral convulsions, this is undoubtedly true; and even the peripheral forms of spasm (*e.g.* convulsive tic) may be shown to have an excito-motor starting point. In all forms of spasms we see, however, that they are essentially connected with the stimulation of the organ of volition or with irritation conveyed through the spinal cord to the periphery. Spinal epilepsy also, as it occurs in paralysis agitans, or in diffuse sclerosis of the central nervous system, and in purely spinal symptoms (as an expression of sclerosis of the lateral columns), is under the influence, on the one hand, of irritation of the voluntary fibres, and on the other of reflex spinal irritation. A localisation of symptomatic spinal epilepsy as an unity would be impracticable. We will return to the probable localisation of paralysis agitans in a spinal section. As a general fact, the following may be stated.

20. The influence of irritation of the sensorium on a phenomenon of motor irritation, and on a pathological motor phenomenon, does not generally prove that this symptom must be of cerebral nature; and motor symptoms of irritation indicated as central are essentially conditional on irritation, or at least co-operation, of the sensitive and sensorial parts of the nervous system. It is generally to be observed that a large group of motor disturbances are not the result of disease of the motor parts (of Bell), but of disease of laterally contiguous parts of the nervous system having motor influence.

I first introduced the fact into pathology, that tabetic motor disturbances were dependent on a regulating motor system having its course within the spinal cord; and Cyon's researches, suggested by me, have made this idea the common property of all. The cerebellum also is a regulating organ of this kind, whose function is as yet little known, but which exercises a stimulating or depressing influence on the performance of the functions of the motor nerves; and motor adynamia is a constant symptom of severe diseases of the cerebellum, especially of its hemispheres. We see, further, that patients with cerebral disease are either drawn to one side, chiefly from unilateral convulsion or paralysis of the muscles of the trunk; or that, at least, there is a feeling of being pulled to one side, which is to be explained by supposing that, in consequence of involuntary increase or decrease of the functional power of the muscles of one side, the muscular sense of equilibrium is destroyed.

We further see, in disease of the hemispheres, that convulsions occur, and, according to the researches of Hitzig and Frisch, that disturbances of the associations of movement take place, which are neither associated into spasm nor with paralysis. The corpora quadrigemina also, with their peripheral prolongations into the so-called motor tract, appear to play an analogous part with regard to motion; *i.e.* their stimulation keeps up the function normally, or produces spastic increase of it, and their paralysis produces disturbance of the motor equilibrium in some way as yet unknown (I imagine that chronic

inflammation of the corpora quadrigemina produces paralysis agitans).

With regard to the localisation of specially associated movements—such, for instance, as occur in chorea major through irritation of portions of the brain, it is to be observed that these parts have the same relation to the movements in question as the claustrum, and that we have reason from analogy to localise the association of movements in the central ganglion. This view is supported by the anatomical fact, that the whole central ganglion, the optic thalami, the corpora quadrigemina, the corpora striata, the lenticular nucleus, and the claustrum, are one connected mass of grey matter; and we may hence conclude that this entire mass possesses analogous functions, and that the centre for the association of movements lies here. As with the claustrum in relation to speech, so with the corpora quadrigemina, it is known that they are the centre of association for the muscles of the eye.

(To be continued.)

DISEASES OF CHILDREN.

ON DIABETES MELLITUS IN CHILDREN.
BY DR. HIRSCHSPRUNG OF COPENHAGEN,* WITH CASES BY DR. BUDDE OF COPENHAGEN,† AND DR. SCHOUBOE OF KALLUNDBORG.‡

(Concluded from page 97.)

Dr. Hirschsprung next relates the case which he himself observed.

12. Marie Petersen, aged eight years, was admitted into the Children's Hospital on September 5, 1872. Her height was 42 inches, and her weight a little more than 37 lbs. (English). She came from a humble home, the conditions of which, however, were tolerably good. She had a sister aged fourteen, in good health, and a brother only four weeks old. Her father was healthy; the mother had always been weak since the patient's birth. She suffered from dryness of the mouth, thirst, and frequent micturition even at night. These symptoms, with her weakened state, led to an examination of the mother's urine, which did not contain sugar. The patient had been nursed by the mother, and was weaned when she was a year-and-a-half old. She walked in good time, cut her teeth without trouble, and seems to have been a healthy and strong child. She had had no other illness than a moderately severe attack of whooping cough in 1870. In the course of the summer of that year she is believed to have fallen off somewhat (but this is not certain), and to have been more thirsty than other children; but she did not ask for drink during the night. It was not, however, until the last fourteen days that, without evident cause, symptoms of disease were observed. She now began to complain of pain in the front of the chest, could not bear to go upstairs, felt always dry in the mouth, was very thirsty, and could eat at any time. At the same time, she began to pass urine very frequently, and in great abundance—eight or nine times in the night in the week before her admission; she slept in the intervals. Micturition was not painful: nor was there any excoriation. She had one or two ordinary stools daily; she had felt dull, and complained sometimes

of headache, but mostly, it was said, of pain behind the sternum. In consequence of her illness she had become somewhat thin; but her strength was still good, and she was well-developed for her age, with blue eyes and fair hair. Her face was rather broad, as was also the vault of the skull; there was no appearance of scrofula; the skin was of pale colour, inclining to blue; the pulse 104; respiration 32; tongue pale, clammy, with a slightly streaked epithelial covering. She was about to change her teeth; several of the milk-teeth were decayed. Her look was lively, and her temper good. There was no disturbance of vision or of any other sense. The temperature was normal. On the right side of the neck there was a weak continuous murmur; otherwise nothing special was heard with the stethoscope. The abdomen was distended, and tympanitic at the upper part; the liver projected an inch forward from the ribs, and reached to the fifth rib. The urine, before treatment was commenced, contained 8.62 per cent. of sugar; its reaction was sour. That passed by day was of a dull yellow colour, a thin layer of it was as clear as water, and the specific gravity was 1.030; that passed at night was yellow, had a stronger urinous smell, and a specific gravity of 1.034.

It would be tedious to give the long uniform daily report of the treatment; and I will therefore merely give a summary of some particulars. The child steadily lost flesh and strength, and died on the last day of the year, having lived between four and five months from the time when the disease was first recognised. In the last weeks, evidence of pulmonary phthisis was observed. In the course of her illness she lost 8½ pounds (Danish) of weight, rather more than a quarter of her weight when she was admitted.

The disease showed quite the same type as we recognise in its most perfect form in adults. It seems on the whole, from the preceding observations, that in the child we do not meet with those milder cases, sometimes spontaneously intermitting, or, at least, readily amenable to treatment, which are fortunately not uncommon in the adult. With its high percentage of sugar, the case was from the first characterised as one of great severity; the percentage was sometimes higher (the maximum being 10.86) while it was never under 5, except on the last days of the patient's life, which presented peculiarities in several respects. The circumstance, that the percentage of sugar could never be reduced below 5, even under an absolutely animal diet, showed that the disease belonged to that form in which the excreted sugar is not only derived from the carbo-hydrates taken with the food, but also from the decomposition of albuminous material; and a further proof of this is approved by the fact that on one occasion the patient took nothing but water for twenty-four hours, during which time the quantity of urine amounted to 500 grammes, and contained 5.44 per cent., or 27 grammes of sugar, which must have been formed at the expense of the tissues of the body.

The amount of urine passed was in proportion to the thirst, which was sometimes unquenchable. The greatest quantity passed in twenty-four hours was 6,000 cubic centimètres (more than 21 ounces by measure). The specific gravity almost constantly ranged between 1.030 and 1.035; on single days only it was as high as 1.040 or as low as 1.027, except during the last days of life.

On eleven days no correct observation was made; during the remaining 103 days of her stay in the

* *Ugeskrift for Læger*, third series, vol. xv. no. 25.

† *Ibid.*

‡ *Ibid.* no. 30.

hospital, she passed 28,470 grammes of sugar (nearly 63 pounds). The greatest quantity discharged in twenty-four hours was 556 grammes (about 20 ozs).

On some days, when she first came into hospital, and also towards the end of life, nocturnal enuresis was reported.

There was obstinate constipation, which resisted the strongest purgatives, during the whole of her life in the hospital. The abdomen was constantly more or less distended and the intestines filled with air, and the ascending colon, but especially the descending and the sigmoid flexure, were felt to be full of scybala.

The temperature was most frequently normal or a degree below, without any fixed type; on some days there was a rapid rise of a degree in the morning or evening, for which no cause could be assigned. During the whole illness there was no disturbance of the nerves, and the patient was conscious nearly to the time of death, which took place without pain.

During the last four days of life, the patient had little appetite, and her thirst was slight. She passed 1,000 cubic centimètres (nearly a quart) of urine daily, which showed a steady decrease of specific gravity and of the percentage of sugar. The urine passed in the last twenty-four hours had a specific gravity of 1.020, and contained 34 grammes (524.75 grains) of sugar. On December 26, the temperature, which was 95° Fahr. in the morning, rose to 104° Fahr. in the evening; it remained high on the following days, and on the evening before death was 105° Fahr., and an hour before death 104°.

In the long period during which the disease was under observation there was ample opportunity for trying the effects of the plans of treatment most recommended. At first, Bouchardat's treatment (animal diet) was followed, in conjunction with the administration of Carlsbad water. This plan appeared to diminish the thirst, and to reduce the amount of urine and the percentage of sugar (the latter, however, never being below 6.25) more than any of the plans which were afterwards adopted. But at the same time the appetite was lost, constipation became extraordinarily obstinate, and after twelve days I passed to the use of milk-diet. After a short time, this had the same result as the meat-diet; she became unable to take the milk, and for twenty-four hours had no food. After this she began to use arsenic (arseniate of soda) with mixed diet. Her appetite became voracious, she ate day and night, and felt comparatively well; but at no period of the illness was the amount of sugar excreted so great as under this treatment. The arsenic was followed by opium, which gave comparatively better results, especially, as it seemed, in producing alvine evacuations; but it made her dull and sleepy, so that she could scarcely move. Glycerine seemed only to make her condition worse; and, at last, convinced of the inutility of every remedy, I gave up all treatment, and, up to the end of her life, allowed her to have whatever gratified her appetite. I give below a view of the average secretion of sugar under the different plans of treatment.

| | Duration in days. | Sugar in grammes daily. |
|----------------------------------|----------------------|-------------------------------|
| Bouchardat's treatment | 12 | 152 |
| Milk diet | 7 | 200 |
| Arsenic | 23 | 364 |
| Opium | 13 | 285 |
| Glycerine | 12 | 292 |
| Ordinary diet | 12 | 331 |
| Do. do. | 2 | 279 |

A necropsy was made twenty-five hours after death by Professor Reisz. Notwithstanding the most careful examination of the organs to which an essential part in the genesis of the disease has been attributed at various periods, the result was simply negative; and the only pathological change consisted in disease of the lungs, which, however, was secondary and did not appear till towards the end of life. No tuberculous deposit was found in these organs; but they presented in the upper lobes pneumonic condensation with bronchial dilatation.

[Dr. Hirschsprung appends to his report a table of observations taken daily from Sept. 8 to Dec. 31, showing the quantity of urine, its specific gravity, the percentage of sugar, the amount of sugar in grammes, and the morning and evening temperatures.]

Dr. Budde reports a case of diabetes in a boy aged eleven, treated with absolute animal diet and glycerine. He says:

As a contribution to the very scanty literature of diabetes in children, I may relate a case, which is remarkable not only because the patient was a male, but because the disease belonged to the milder form, in which the discharge of sugar may be prevented by an absolutely animal diet; and the treatment adopted was followed by as complete recovery as can take place in diabetes. All the cases hitherto reported have belonged to the more severe form; treatment has had little or no effect; and death has occurred in all in a comparatively short time.

The patient was a boy aged eleven, from one of the chief towns in Funen. There was no hereditary tendency to disease in his family, and he himself had hitherto always enjoyed good health. Early in December, 1872, without any apparent cause, he began to suffer from thirst and polyuria, had nocturnal enuresis, and rapidly became very dull and weak. The disease became rapidly worse; he complained of unquenchable thirst; the discharge of urine became excessive; micturition was very frequent both by day and by night; and, in spite of eating voraciously, he lost flesh and strength more and more. In short, the symptoms assumed a very threatening character, and the medical men who had been consulted sent him to me.

He was much exhausted by the journey; and was so prostrate and weak, that he could scarcely stand upright. Emaciation was excessive; the muscles were thin and relaxed; the skin was dry and rough, the tongued and dry, with prominent papillæ. The lungs were healthy, the liver was not enlarged. The urine presented the ordinary characters of diabetes, and contained eight per cent. of sugar.

It is evident that I could only form a very unfavourable prognosis, partly because this is generally bad in diabetic children, partly because the disturbance of nutrition had become so severe, and finally, because the amount of sugar in the urine was so great. With regard to treatment, it might be considered fortunate that his appetite was good, and that the digestive functions were unimpaired. There was, therefore, hope that the use of a purely animal diet might restore nutrition, and at the same time more or less reduce the glycosuria. I therefore ordered a diet of this kind, adding glycerine, in doses of 30 grammes (about an ounce) daily, in 200 grammes of water and 5 grammes (76 grains) of tartaric acid; a medicine the use of which I had several times seen to be attended by benefit.

The results of this treatment were good beyond all expectation; all the diabetic symptoms were soon

relieved, the thirst and polyuria completely disappeared, the muscles increased in size, and he felt himself again strong and well. The sugar in the urine fell on the tenth day to two per cent., and on the eleventh day the urine contained no sugar.

Five days after the commencement of the treatment, he weighed $61\frac{1}{2}$ Danish pounds; a fortnight later he had gained 14 pounds, and at the time of the report he weighed 80 pounds. He is now well, and has a healthy and robust appearance; but two slight errors in diet which he has committed have shown me, that the glycosuria returns under the use of a comparatively small quantity of carbohydrates. I am endeavouring to find out the diet which suits him best, and especially how much saccharine and starchy food he can use without a return of the glycosuria.

Dr. Schouboe writes as follows.

The daughter of a small farmer, seven years old, the only child of parents in tolerably easy circumstances, residing in a healthy home, having a somewhat delicate appearance, had in August, 1872, a febrile attack—heat and sweating alternately with cold; at the same time she had severe cardialgia, and the bowels were rather constipated. She had been more or less ailing for a year. Under the use of quinine and iron she was better in about a month; but she again had pain in the abdomen, which was hard and distended; the stools were solid, usually covered with bloody mucus. There was no trace of fever, but she was always very thirsty, and had a great appetite. She passed much urine, especially at night, and often was thus prevented from sleeping until the morning; in the forenoon, the discharge of urine was less. When examined on September 19, the urine was of tolerably natural appearance, but contained an abundance of sugar. She was now put on a nearly absolute animal diet, with a small quantity of bread containing bran; for drink she had claret and water, a little milk and water, and a little coffee (without sugar). Quinine and iron were prescribed; also opium and laxatives. Under this treatment she became better; her appetite was less voracious, the thirst diminished, and the diuresis was so far decreased that she often passed urine only once in the night. The stools were also improved, and were no longer bloody; her strength increased, and she did not complain of pain in the abdomen. The quantity of sugar in the urine was less. She continued in this state until December, when I again visited her. She again had pain in the abdomen, which was harder (there was no sign of a tumour at any time); the stools were solid; the diuresis had not increased, nor had she thirst. There was a little albumen in the urine, tending to an increase of sugar, and there was slight œdema of the face and hands. She again became better, and in January could often sleep all night without being disturbed to pass urine; the sugar decreased, and the albumuria and œdema disappeared. In February, after she had been about a fortnight without medicine, her condition was fairly good, and she was able to go out when the weather was mild. The appetite and thirst were somewhat variable; sometimes they increased (always together) and soon again became natural. In March she again became worse; the diuresis and thirst increased, as well as the quantity of sugar, and she lost appetite and strength; she was somewhat susceptible of cold, and usually had headache, but was not confined to bed until the last days of her life. On the 29th, it was reported to me that

she had been much worse for two days. I therefore visited her the same evening, but found her already *in articulo mortis*, cold and pulseless, with very difficult whistling respiration. I learned that she had sat up two days previously, but on the following day had violent dyspnoea, with some cough. She was conscious till the evening, when she began to be delirious and afterwards fell into a state of coma. She died the same night.

During this rather long illness, neither cataract nor gangrene was observed. The urine was tested for sugar every two or three weeks, but no quantitative analysis was made. The quantity of urine was not measured; the mother only stated how many potsful had been passed in the day. The analysis and measurement necessary for a true accurate history of the case could not be well carried out, as the patient lived in the country, and could only be heard of or seen at long intervals.

SURGERY.

VALERANI ON OPERATION BY THE BLOODLESS METHOD.—Dr. Valerani reported to the Royal Academy of Medicine in Turin, on December 22, some cases in which he had operated by the bloodless method (*Gazetta delle Cliniche*, no. 52, 1873). The first case was one of amputation of the arm in a young woman, in whom poverty of blood and debility rendered it necessary to avoid the least loss of blood. A vast sloughing ulcer had laid bare a great part of the right humerus; and, in spite of all treatment, there was reason to fear that the process of destruction would extend to the blood-vessels and produce hæmorrhage. The bone was in a state of necrosis, and was bent on itself. Although it was not possible to apply a bandage, as if the limb were sound, Dr. Valerani tried elastic compression; and, having driven out the venous blood as well as he could, and tied the elastic tube round the limb at the upper part, he amputated the limb by the circular method close to the surgical neck of the humerus. In spite of the difficulty of applying the elastic bandage, the result was very satisfactory, a few drops only of blood being lost. Nothing afterwards occurred to interrupt the favourable progress of the case.

Dr. Guaschino had applied the elastic bandage in a case of amputation of the leg for severe disease of the tibio-tarsal joint. He affirmed that he performed the operation just as on the dead subject.

Dr. Valerani reported also another case, showing the value of elastic compression, not only in amputation but in other important operations. A woman aged forty-five, from Casale, was admitted into hospital under his care, on November 19, with an aneurism on the left popliteal space. She first perceived it little more than a month previously, and it had increased rapidly, producing tingling in the limb, and impeding motion. Her general health was very good; but menstruation had ceased rather early. She had had one child when she was about twenty-three or twenty-four years of age, and had had no illness of importance. The aneurism was of the size of a large fist. Digital compression for three or four hours at a time was tried for some days; but, as this was troublesome to her, and there was a deficiency of a sufficiently intelligent staff of assistants, it was determined to tie the femoral artery. The compression had, in the meantime, led to enlargement of the

collateral branches, and has thus placed the limb in a more favourable condition for operation. The ligature was applied on November 25, in the apex of Scarpa's triangle. Before the operation, an elastic bandage was applied to the limb, and compression made by the elastic tubing at the upper part; by this the tissues were rendered almost exsanguine, and the vessel was easily found, though buried in a thick layer of fat.

The priority of the method, generally attributed to Esmarch, is claimed by the Italian surgeons, as well as the elastic ligature described by Dittel, for Dr. Grandesso Silvestri. A. HENRY, M.D.

MENZEL ON REMOVAL OF THE TONGUE BY A MODIFICATION OF REGNOLI'S OPERATION.—Dr. Menzel, of Trieste, describes (*Gazzetta Medica Italiana-Lombardia*, no. 2, 1874), two cases of removal of cancer of the tongue. In his introductory remarks, he says that, while Regnoli made a longitudinal incision from the chin to the hyoid bone, and another along the lower edge of the jaw, thus, , Czerny has modified the operation by omitting the longitudinal incision, and ties the lingual artery. His incision has this shape . Billroth, in ten cases on which he has operated, has also made only the semi-elliptical incision; he ties the lingual artery in the wound itself, before excising the tongue. Dr. Menzel, in his cases, followed Czerny's modification.

The first case was that of a man named Lodovico Vogelhaupt, aged sixty, tall, rather thin and pale, who was admitted to hospital on April 3, 1873. For three months he had had difficulty in moving the tongue, and complained of very severe pain in the left occipital region. At first sight the tongue appeared healthy; but, on pressing it down with a spatula, the margin behind the left palato-glossal arch was seen to be irregular, tumid, and somewhat ulcerated; and the part was felt by the finger to be the seat of rather extensive induration. The next day, the patient having been narcotised, Dr. Menzel tied the left lingual artery, having made an incision parallel to the greater cornu of the hyoid bone. A semi-elliptical cut was then made along the edge of the lower jaw, and was carried down on the left side to the incision made to reach the lingual artery, so that the incision had this form . The floor of the mouth was then cut away from the lower jaw, and the tongue was drawn out by Museux's forceps. As the affected part, however, was not sufficiently brought into sight, the cancer extending behind the palato-glossal arch, Dr. Menzel divided this with two strokes of a pair of scissors. This enabled the tongue to be brought well forward, and the left half of the base of the tongue, with the diseased mucous membrane, was removed by means of scissors. Scarcely a drop of blood was lost. The patient recovered from this operation; his deglutition was free, and his speech somewhat impeded, but intelligible. He was able for a time to follow his occupation as a carpenter, but was again admitted into hospital six months after the operation, with a return of the disease.

The second case occurred in a sailor named Spirdione Muisan, aged sixty-five, who came into hospital with cancer of the tongue of five months' standing. The whole base, posteriorly to the palato-glossal arches, was knobby, hard, and ulcerated, mostly on the left side. The patient was the subject of emphysema and bronchial catarrh, and had had three

long attacks of ague. Dr. Menzel, having narcotised the patient, made two incisions, parallel to and above the hyoid bone, and tied both lingual arteries. He then cut into the cavity of the mouth by a semi-elliptical incision along the jaw, and removed the whole tongue close to the epiglottis. The patient appeared to be going on well, when, on the thirtieth day, the bronchial catarrh and dyspnoea increased, diarrhoea set in, and he died two days afterwards.

Dr. Menzel remarks that complete extirpation of cancer of the base of the tongue, even extending to the adjacent parts, may be performed easily by Regnoli's method, and that this operation affords hope in many cases of cancer which would formerly have been abandoned to their fate. Langenbeck has observed that the prognosis is more favourable in extensive than in limited cancer of the tongue; no doubt because in the latter case surgeons have been accustomed to remove the sound tissues too sparingly. In cases of cancer of the breast, most surgeons remove not only the tumour but the whole breast, including the skin; and local returns of the disease are more rare and slow than in the case of the tongue. It would perhaps be wise to proceed in the same way in cancer of the tongue, and to remove the entire organ in all cases.

Regnoli's method seems to Dr. Menzel to afford the advantage of allowing the escape of secretions from the mouth. A. HENRY, M.D.

PANAS ON SECTION OF THE BUCCAL NERVE BY THE MOUTH.—Dr. J. Panas, surgeon of the Lariboisière, has communicated to the Academy of Medicine (Dec. 23, 1873) an account of the section of the buccal nerve from the mouth, with operative rules, which, he says, are not given in books of operative surgery.

Only one procedure has been described thus far, and by this the nerve is sought for by dissection from the skin to the deep surface. It may be described as the proceeding of M. Michel, of Strasbourg, who first in 1856 performed section of the buccal nerve. A description of it is found in the theses of Voisard (Strasbourg, 1864) and in those of Gaux (Strasbourg, 1866) as well as in the work of Letiévant (*Traité des Sections Nerveuses*, 1873). According to M. Panas, Nélaton made the first attempt to divide this nerve from the mouth in 1857, and this procedure was repeated a second time by Nélaton in 1864 (*Bulletin de Thérapeutique*), but of these efforts there remains no trace in rules for the performance of the operation. M. Panas has now drawn up the following description of the operation of intrabuccal section.

First Stage.—The patient being seated facing the light, and having the mouth largely opened and well-lighted by the aid of Lier's gag, applied at the commissure on the side of the operator, the surgeon places the extremity of his left index finger towards the middle of the coronoid border of the jaw. He makes a vertical incision two and a half centimètres long, parallel to his nail, commencing at the middle of the last upper molar, and terminating at the last lower molar. This incision should only divide the mucous membrane.

Second Stage.—The buccinator muscle being thus uncovered, all the fibres seen are divided vertically layer by layer, in such manner as to avoid injuring the buccal nerve immediately subjacent, and the fatty pad of the cheek.

Third Stage. The nerve is then looked for. It passes

transversely from behind forward, following a line drawn from the coronoid border of the jaw and terminating at the commissure of the mouth. A little blunt hook passed into the middle of the incision, made according to the preceding rules, enables the nerve to be found easily, after which it is divided by a pair of blunt scissors curved on the flat. The only vessels of any importance which are necessarily opened, are, the buccal arteriole and venule, satellites of the buccal nerve. Torsion arrests hæmorrhage. The little jet from this artery, and the sensation from pulling on the nerve, easily convince the operator that he has found the nerve; the loss of sensibility following the section confirms the evidence of the completion of the operation. In order to be sure of dividing all the filaments of the buccal nerve, it is well to incise the buccinator to the whole extent of the wound made in the mucous membrane, and, if necessary, even to penetrate the fatty cushion of the cheek. The advantages of this method are: that it is quick and certain; that it produces no cicatrix and avoids deformity; that no risk is incurred of wounding the facial artery or Stenon's duct. M. Panas has performed the operation, with facility and with a result successful for the time at least, on a woman suffering from obstinate neuralgia of twelve years standing. In all, M. Panas enumerates only seven operations of this sort: two of Michel, one successful; two of Nélaton, one successful; two of Letiévant and Vallette, one successful. The results of the operation then are uncertain, but there is encouragement to employ it in desperate cases.

PETER ON POLYPIFORM VEGETATION OF THE TRACHEA AFTER TRACHEOTOMY.—Dr. Peter called the attention of the Société Médicale des Hôpitaux, on December 26, 1873 (*L'Union Médicale*) to the details of a case in which tracheotomy had been successfully performed on a child aged three, attacked by croup. The cannula could not be removed for three months, as each attempt to do so produced an access of suffocation. Finally it was removed; but it was observed that in any rapid effort, or in attacks of anger or alarm, suffocative dyspnoea was brought on. Finally, in such an attack, the child died suddenly. There was found at the inferior angle of the tracheal cicatrix a polypiform vegetation, incapable itself of giving rise to suffocation and death, but capable of exciting fatal spasm. M. Bergeron related a similar case; and in the course of the discussion which followed many remarkable cases were mentioned, indicating that small growths, at a distance from the vocal cords, are capable of exciting distressing and even fatal accesses of laryngeal spasm; and that sessile granulations, at the seat of a tracheal wound require careful attention before the cannula is withdrawn after tracheotomy.

JULLIEN ON AMPUTATION OF THE PENIS.—Dr. Jullien (Paris, Delahaye, 1873), discusses completely the history of the operation, and recommends that the section of the skin should be made at the same level as that of the corpora cavernosa, employing for the purpose the method of Desgrange 'who is always careful to place behind the line of intended section an enterotome, the branches of which embrace firmly the whole thickness of the organ.' He is strongly in favour of the actual cautery, which has given excellent results at Lyons, where the author practises. To avoid stricture, however, it is prudent to employ the V-shaped incisions (Ricord).

He objects to leaving a sound in the urethra, as being a source of injury to the passage and bladder. His mortality is one in 20.

OBSTETRICS AND GYNÆCOLOGY.

UNGARELLI ON A CASE OF CÆSAREAN SECTION. Dr. O. Ungarelli, of Minerbio (*Bullettino delle Scienze Mediche*, and *Gazetta delle Cliniche*, no. 48, 1873), relates a case in which he performed the Cæsarean operation, or gastro-hysterotomy, by what he describes as a new method, after having made an accurate diagnosis of the position of the fœtus. The patient was a woman, aged twenty-seven, with deformed spine and pelvis, who had been in labour forty-four hours when Dr. Ungarelli was called to her in consultation by Dr. Quercé, whose patient she was. He thus describes the operation.

In ordinary cases of labour, when it is necessary to perform versions besides examining the parts through which the fœtus has to pass, I always examine the uterus from the exterior, so as to find on what side the feet lie and to be able to introduce the hand in that direction; and in many cases I have found advantage from this, after having introduced the hand into the uterus. I determined to make an examination of the kind on this patient before proceeding to perform the Cæsarean operation, in the full confidence that, by making the incision where the feet are felt, it might be limited as much as possible. Preparations having been quickly made, and the patient placed on a miserable little bed, the only one which her dwelling offered, I made with a bistoury an incision 9 centimètres ($3\frac{1}{2}$ inches) in length over the left colic region, where the feet were felt, dividing in succession the skin and the muscles as far as the peritoneum. Two arterial twigs, branches of the epigastric, spouted blood, and were at once tied. I then divided the peritoneum on a director. A loop of intestine, partly covered by omentum, presented itself at the upper angle of the incision, and was replaced and held back by my assistant, so as to enable me to make an incision in the uterus of the same extent as that in the integument. All this was done as quickly as possible; and I had scarcely cut through the uterus when a foot escaped, and immediately afterwards another; they were both seized, and the entire child was withdrawn alive by my assistant, while my attention was directed to preventing the uterine fluids from escaping into the cavity of the abdomen. The placenta was easily removed. The wound in the abdominal wall was united by suture, and plaister and a compress were applied. The woman recovered. A. HENRY, M.D.

PUBLIC HEALTH.

HEALTH-LAWS AND THEIR ADMINISTRATION.

Since the passing of the Public Health Act of 1872, the appointment of a large staff of sanitary officers in all parts of the kingdom has given an impulse to the sanitary movement, and to preventive medicine a significance not secondary to that of the curative treatment of disease.

Medical practitioners are now called upon to per-

form new functions, demanding varied and extensive knowledge and experience yet immature. Old ideas of medical practice are undergoing a revolution, and changes not less welcome to practitioners themselves than beneficial to their patients are in progress of development.

Sanitary, social, and municipal policy affecting public health, are not yet sufficiently in the course of teaching in our medical schools, and the practical application of the sanitary laws is as yet too little known to many who are now called upon to administer them.

With the view of bringing Sanitary Science and Practice more prominently under the notice of the profession and the public generally, especially those interested in sanitary science, and now fulfilling high positions in connection with local sanitary boards, we purpose devoting special attention to matters affecting domestic and public health. The interest taken by the public and those of our readers engaged in official sanitary work, warrants the enterprise now proposed of making the *LONDON MEDICAL RECORD* a medium in which sanitary administration, sanitary education, sanitary appliances and inventions shall be an attractive feature, worthy of their study and attention. The information which in future will be found in this department of the *LONDON MEDICAL RECORD*, while it cannot fail to be conducive to the advancement of practical hygiene, will also furnish abundant material for that numerous circle of readers in the community at large, who watch with interest every effort to extend sound popular knowledge on all subjects closely affecting domestic welfare and happiness, and especially that which concerns the

'Mens sana in corpore sano.'

SANITARY EXHIBITIONS.

The International Exhibition of 1874.

Since the displays of 1851 and 1862 in the form of grand exhibitions, the tendency has been to collect objects of interest into smaller and more defined groups; and, in harmony with the spirit of the times, we find sanitary exhibitions taking a very prominent place.

At Leeds, in 1871, not the least important feature of the Social Science Congress was a sanitary exhibition, which, although got up in a hasty manner, succeeded beyond the most sanguine expectations of its promoters and exhibitors; and at Norwich, last autumn, the same experiment was a success, both as a financial and a social scheme.

Preparations are also making at Glasgow (we understand) for the renewal on a larger scale of a sanitary and domestic exhibition during the sittings of the Social Science Congress in that city.

Mr. Thomas Twining of Twickenham was, we believe, the first who started the idea; and, although his museum of sanitary and domestic economy with the whole of its valuable contents were destroyed by fire three years ago, and so lost to the public and its proprietor, there are signs of his labours still yielding good fruit by passing into other hands able to continue the work which he commenced.

The London International annual Exhibitions, conducted by the commissioners of the 1851 Exhibition, will this year open on Easter Monday; and among the classes 9 and 10, of manufacturing machines and processes, sanitary works will occupy the foremost rank.

The increasingly large circle interested in these displays of objects so closely concerning domestic comfort and personal health, and the eagerness with which persons examine anything under the head of sanitary appliances, is a manifest sign of a progress in the present generation, towards the taste for a study and cultivation of the hygienic laws and their practical applications.

We intend shortly, as the occasion offers, to consider these matters in the new light of modern science.

The International Exhibition, 1874, promises to attract a large share of interest from the medical profession as well as from the public, as may be predicted from articles exhibited under the head of civil engineering, architectural and building contrivances, sanitary apparatus and constructions, heating and warming by all kinds of fuel, and ventilating by all methods.

Sanitary officers, including now the large staff of medical officers of health, inspectors of nuisances, besides the chairmen and members of sanitary boards elected in all parts of the kingdom, called upon as they are to exercise sanitary functions, must of themselves form a large body of critical observers and anxious inquirers into these branches of sanitary industry, and become acquainted with modern improvements relating thereto. Every article exhibited in this department will be especially interesting to enable them to carry away that kind of information available in their official work. From them we hope to get valuable opinions regarding the class of disinfectants, and disinfecting processes, if exhibited as we trust they may be.

As we purpose in future pages of the *LONDON MEDICAL RECORD* to enter into full and special details of the various objects, processes, new inventions, and sanitary appliances about to be exhibited at the International of 1874, we will here only glance briefly at the character of the articles likely to call for a critical examination in a sanitary point of view.

Under the heading of sanitary architecture, we shall find model houses and cottages (and, as usual, the improved dwellings for the industrial classes, of which we hear so much, and make so little progress in providing), all kinds of building materials, stone, bricks, tiles, concrete, and cement; flooring and paving, ornamental and useful designs for buildings of large and small elevation.

In water-supply and drainage materials, the exhibition of 1874 will be particularly rich and complete. Every variety of manufacture in metal, porcelain and glazed earthenware tubing or pipes will be seen; several kinds of filters, water-waste preventers, taps and apparatus for the constant supply service (not yet understood in the metropolis) and in which great improvements and adaptability for household convenience will have to be made. In works of town drainage, scavenging and cleansing of streets, it is believed new suggestions (not before they are wanted in London) will be forthcoming for the collection and removal of excreta and refuse of towns. The dry earth conservancy system in many forms, along side of the best methods of civic purification, it is expected, will be well represented by practical methods by more than one exhibitor.

Companies recently established for carrying out sanitary works on a large scale will exhibit their methods; amongst other things, sewage purification by actual operation and demonstration, with

recent sewage, both by the wet and dry earth systems, by the charcoal filtration or otherwise, may be examined. Urinal and closet accommodations, and various other proposed methods of dealing with the excreta of towns and villages, will be seen. Diagrams, plans, sections, and models of sinks, traps, sewers, and ventilating apparatus will receive special notice, and have from us a minute examination. In future numbers of the RECORD it is proposed to point out the peculiar merits of each article or invention most worthy of attention; indeed, sanitary appliances for promoting domestic economy will be a distinguishing feature of one department of this journal, and if not extending, as we believe it will do, the domain of medical practice in the direction of preventive medical service, it will at least gratify us in complying with the request of a numerous class of readers devoted to the cultivation of sanitary science and to the promotion of the public health.

SANITARY INSPECTORS OF NORTH-AMPTONSHIRE.

The sanitary inspectors of this large area, being a combination of many rural and urban sanitary authorities, at the invitation of Mr. Haviland, the Medical Officer of Health, met recently at Northampton to express opinions and interchange experience. This was a wise course, and ought to be generally followed elsewhere. Such meetings of sanitary officers will be able occasionally to advise the governing bodies on many points in the Public Health Act of 1872, showing where it has failed and will fail to effect its purpose. They are well able to contribute to its amendment and final successes. Mr. Haviland told his inspectors that a great many old and absurd notions would have to be exploded, such as the following.

‘Many people on going into a village point out this man as eighty, and that man as seventy-five, or another who had lived to be one hundred years old. Long life was never yet a criterion of a healthy village. It was the life of the young people. Let them tell him the life of the young and show that they lived, and he would say whether their village was a healthy one. When once people got to a certain age they would live a long time. But it was the young they had to look to, the young in over-crowded houses with bad food and bad water were the objects of their special care. In our age there was a certain amount of vitality still left, whilst they were not overstrained and the excitement of life had passed; so that life went on if there was no particular accident or disease of an epidemic character to carry them off. The estimating the healthiness of a village or town by the length of life of some persons only was a perfect fallacy. Without having many deaths they might have much illness, as at Maidford, where not a single death occurred from typhoid, yet the death-rate is higher than Manchester or Liverpool.’

Mr. Haviland stated that his experience of sixteen sanitary inspectors did not lead him to wish to alter his relations with them, and as far as he was concerned his wishes were always carried out; and therefore under the circumstances, he did not desire any change. He wanted no further service than that which had hitherto been accorded, and accorded, he believed cheerfully. With regard to the water-supply, he suggested to the inspectors the advisability of studying geology and getting a practical acquaintance with the nature of the soil, nothing was more profit-

able, or more delightful for them whether they walked or drove on their rounds. This kind of experience associated as it was with drainage-works, would get them a position better than many testimonials. He cited an instance. An inspector, perfectly ignorant of his work, and disregarding levelling, ran up a bill for drainage of 600*l.* or 700*l.* by undertaking what he knew nothing about. He told the inspectors, very properly, that a knowledge of the geological formation of the soil and of well-sinking was of that practical kind which enabled them to judge of what was right to do and how to carry it out. They must make their office, for their office would not make them. This is very true, for a new class of men are springing up and being educated for their work, and it is a most excellent step in the right direction that they should combine themselves into associations like this and endeavour to co-operate with each other to promote their own interests, and that of the public health. Mr. Haviland deserves thanks for initiating this movement.

FOOD ADULTERATION AND ANALYSIS.—Dr. Hardwicke (*Third Quarterly Report of the Public Analyst for Paddington*) states that most of the articles analysed were, at the request of the Sanitary Committee, purchased by the inspector, and brought for analysis; there were also other articles given to him by persons in the parish and submitted officially for analysis.

Forty-two articles were examined during the quarter ending December 25.

Spirits.—In November and December, twenty-two samples of wines and spirituous liquors were procured by the inspector. Few only were of an inferior quality, and four were diluted before being sold to the retailer. The highest amount of alcohol was in the brandies and whiskies, the lowest in the gin and rum. The brown brandies were nearly all coloured with burnt sugar, and had distinct traces of molasses and cane-sugar. Amylic alcohol, or fusel oil, may be detected in some of the brandies and whiskies; but the samples submitted were not sufficient in quantity to make a separate estimation. It was probably a natural production of distillation, and not an adulteration; for according to Liebig, this substance is formed during the fermentation and distillation of saccharine liquids where gluten or any other nitrogenous substances are present. Where, however, the fermentation of saccharine matter is from pure grape-sugar, this impurity is not present to any great extent.

Vinegar.—Three samples of vinegar were diluted and wanting in the normal quantity of acetic acid; one had five per cent. which might be taken as the usual quantity. They were coloured with burnt sugar and contained common salt and sulphuric acid, in minute quantities. The common vinegars at 4*d.* per pint were made up with acetic acid of wood distillation. There were few samples of pure malt vinegar in the market.

Wines.—Officially, Dr. Hardwicke had had only five samples of wine, three of port, one of sherry, and one of marsala. The sherry contained sulphates of potash, alum, and lime, showing that in the process of manufacture the wine had been cleared by using gypsum or ‘Spanish clay’ (sulphate of lime). This form of adulteration is not injurious. The average alcoholic strength of the wines was fifteen per cent.

Ales.—Seven samples of ale examined varied in price—4*d.*, 6*d.*, and 8*d.* per quart. Those of the highest prices were clear and bright, showing no change or sediment after being kept corked up several days. The cheap ales had a sedimentary deposit, consisting chiefly of yeast-plant in a growing state, with other organic impurities in a state of fermentation. Dr. Hardwicke regards these as dangerous to drink, especially in epidemic seasons. The alcohol varied from 3·5 to 10 per cent.; the solid residues consisted of saccharine and bitter extractive matters, 3 to 10 per cent. 'There are strong reasons for believing that some ales are fortified by the addition of alcohol, in some manner, giving to them an unnatural intoxicating tendency.' He did not detect any dangerous adulteration, sulphate of iron, &c.

Bread.—Forty samples of bread sold in the parish were brought for analysis. Throughout the parish bread in most excellent quality is sold in the shops; but alum was occasionally found in bread, muffins, and crumpets, in such an amount as to preclude the possibility of its being there as a natural product. A minute quantity of alumina which, like silica and lime, comes from the soil, may exist in the ashes of the cereal plants. In the cases where Dr. Hardwicke has reported alum to have been used as an adulterant, it has been found as hydrate of alumina, in quantity exceeding half of a grain in 1,000 grains of moist bread, that is equal to fifteen to forty grains of alum in a 4 lb. loaf. 'The question of its injuriousness to health in small quantities, as well as of its necessity to enable inferior flour to be made into bread, is involved in obscurity; and, sooner or later, bread analysis will lead to a discussion in which public analysts, medical men, and even the bakers will have a good deal to say. I should not recommend the vestry to be the pioneers in expensive litigation before magistrates, but wait until the legal and sanitary aspect of the question has been a little more matured. I am prepared to enter fully into the matter, and to prove that alum exists in the cases I have reported; although there is reason to believe the practice has since been given up, not only in some of the best shops, but also in what are called the cheap bakers, or of "cutting shops" in the trade.'

Milk.—Six samples of milk were examined officially. The inspector procured them from street-hawking milkmen going round on Sundays and at night. They were much complained of, and the samples were most of them very bad. Four were recommended for prosecutions, having from twenty-five to forty-five per cent. of water in excess. The specific gravities of these inferior milks varied from 1,018 to 1,026, the normal standard being 1,032. The solid matters were as low as eight and nine per cent. instead of twelve and thirteen. The cream was also proportionately low. In the examination of other specimens during the past quarter, the milk distributed in the parish was of a fair quality; still it was below what the standard ought to be. What the average should be, has not yet been determined; and the dairymen have expressed a desire to hear what officers of health and public analysts have to say on the subject of a decided standard, so that milk-purveyors may only sell the best milk now the price is raised. There are no valid reasons why milk in perfect condition should not be sold at 5*d.* per quart. Milk ought not to show a lower specific gravity than 1,030 to 1,032, and the cream should

be not less than from eight to twelve per cent. (for it may vary considerably in the same cow at different times); the solids which show the nutritive value, should be not less than twelve or thirteen per cent.; anything below that, if occurring frequently, would indicate a want of proper attention to the feeding of the cows, or adulteration with water, or the creaming of new milk. The purveyors ought, to undertake the responsibility of testing the quality of milk supplied to the public, whether from 'country farms' or 'shed milk,' also of looking after the health and condition of cows; the latter duty is incumbent upon them, and will be the only guarantee for securing richness and purity of milk. It is also desirable that the dairies and places where milk is kept for sale previously to distribution, should be inspected by the health-officers of the district. Pumps and surface-wells of a dairy should be periodically examined, for typhoid epidemics have been attributed to the poisoned water of foul wells, used for washing the milk utensils.

Milk itself, like water, will readily absorb atmospheric poisons, and spread disease; therefore the emanations of a foul drain, untrapped sinks and closets, a damp unwholesome basement in a house, are very dangerous in proximity to milk exposed to them. I would refer to my paper for further details.*

Dairy reform will therefore consist in—1. Inspection of dairies, of the feeding of milch cows, and of the state of their health; 2. More speedy delivery to families of the pure new milk after milking; 3. The fixing of a standard guaranteed quality of new milk, by testing and analysis.

THE ADULTERATION OF BUTTER.—At a meeting of the Society of Medical Officers of Health, held at the Scottish Corporation Hall, under the presidency of Dr. Hardwicke, a paper was read by Dr. C. Meymott Tidy upon 'Butter and its Adulterations.' Dr. Tidy said that butter was generally prepared from cream collected from time to time and allowed to become slightly sour. It was then churned. The best temperature for churning was from fifty to fifty-five degrees Fahrenheit, and hence most churns had an outside vessel either to warm or cool the apparatus. Churning should not be too slow, or the flavour of the butter would be entirely destroyed, nor too fast, or the butter would be soft and frothy. Butter was also made from fresh cream and from entire milk. This should stand until it was sour, and then be churned at a temperature of sixty degrees. More butter was obtained from entire milk than from cream, but there was more work in the churning. Milk on an average yielded from 4·5 to 5·5 per cent. of butter; a cow yielded about one pound of butter daily. It was next taken out of the churn and washed with water, to remove the whey, as the butter would otherwise decompose more rapidly. It was then salted, about four per cent. of salt being a fair quantity to be added. The amount of stearine, oleine, and palmitine in butter was practically *nil*. The first adulteration of butter was water. By drying 100 grains of pure butter in a weighed capsule for several hours at 220 degrees Fahr., from five to eight per cent. of water would be produced. Water was incorporated with the butter chiefly when it was semi-solid, and also by beating out and sprinkling. Of 130 samples of butter purchased at different shops in Kent, seven contained from seven to nine per cent of water, twenty-one from nine to ten per cent., thirty-four from ten to thirteen per cent., forty-two from

* 'On the recent Outbreak of Typhoid in Marylebone,' by W. Hardwicke, M.D., in the *Social Science Transactions, Norwich Congress, 1873.*

fourteen to seventeen per cent., seventeen from eighteen to twenty-four per cent., and nine over twenty-five per cent. It was his custom, in official analysis, to state the amount of water over ten per cent. The next adulteration was salt. To trace this the remainder of the 100 grains used for drying is incinerated. In twelve specimens of undoubtedly pure butter, the average amount of salt traceable was 5.2 per cent., and of twenty-seven samples of butter indiscriminately purchased, he found that two contained less than three per cent. of salt, two between three and four per cent., three between four and five per cent., four between five and six per cent., ten between six and seven per cent., two between seven and eight per cent., one between eight and nine per cent., two ten per cent., and one seventeen per cent. Over seven per cent of salt he considered excessive. Adulteration was also produced by the addition of dripping, lard, suet, and other fats. These could only be mixed with butter when they were cold, and hence the mixture was never perfect. The fats, unlike real butter, contained stearine, palmitine, &c., in considerable amount. The presence of these fats was denoted by the melting and solidifying points. Butter melted upon an average at seventy-five degrees, and solidified at sixty-three; dripping melted at 79.5, and solidified at 72.5; and suet melted at eighty-two, and solidified at seventy-five. The taste of real butter could be detected, even when it had been most extensively mixed. Pure butter melted quickly on the tongue, and there was no sense of granulation; but when adulterated with other fats it melted far more slowly, and a peculiar granulated feeling in the mouth was produced as the last few grains disappeared. The odours of butter and of dripping were easily distinguishable, but the smell of lard when mixed with butter was not so soon detected. Good butter was generally of a rich yellow colour, entirely uniform; but when adulterated the colour was very much paler, and it was marbled, owing to the imperfect admixture of other fats. He regarded streaky butter generally with suspicion. In good butter an uniform surface was produced by passing a clean knife rapidly over it, but impure butter had a granular appearance. Dr. Tidy concluded by describing other more technical ways of detecting bad butter, such as the action of ether and the use of the microscope with polarised light. The Society passed a cordial vote of thanks to Dr. Tidy for his interesting remarks. A short discussion ensued, in which Dr. Stevens, Dr. Bernays, and Dr. Tripe joined. Dr. Bernays observed that from five to six per cent. of water undoubtedly improved butter, and the addition of more than seven per cent of salt would render it uneatable. When in butter of 1s. per pound he found no less than 22½ per cent. of salt and water, he could not think it cheap.

ADULTERATION OF FOOD ACT—PROSECUTIONS.—At the Southwark Police Court, Sarah Duckett, of Albert Street, Bermondsey, was summoned at the instance of Mr. Dorman, an officer of the Bermondsey Vestry, for selling milk adulterated with 40 per cent. of water. The defendant said she sometimes obliged a neighbour with a small quantity of milk which she had diluted, but she was not in the habit of selling it. On the day in question the man brought a bottle and asked her for a pennyworth, and she served him with it. Mr. Dorman said he had seen people come out of the house with milk, and on one occasion he tested it. Finding it was very much diluted he took the present proceedings. Mr. Benson fined her 10s. and 17. 13s. costs, and told her if she came again she would be liable to a penalty of 20s.

At the Tonbridge Petty Sessions, a person named Featherstone was charged with selling bread adulterated with alum. The inspector produced a certificate from Dr. Tidy, stating that in the sample 2 lb. loaf left with him there were 14.8 grains of alum. The man who always made the defendant's bread was called. He deposed that no alum was ever used by defendant, who was a contractor under Government for supplying the Royal Engineers in

the town. The same bread was served out to them as to the general public. The second officer in command said the defendant's bread was tested from time to time, by the War Office chemist at Woolwich, but no trace of adulteration had ever been found. Mr. Warner asked that the case should be adjourned to enable him to have an independent test. The Bench refused, saying they were willing that Dr. Tidy should re-analyse the half loaf produced in Court. The defendant could not see that it was at all likely Dr. Tidy would alter his opinion. The Bench fined him 10s. and costs.

At the Greenwich Police Court, Mr. Martin, baker, of Mason Street, New Cross, appeared to an adjourned summons for selling bread adulterated with alum. There had been two analyses. The first, made by the local analyst, showed that there were 45 grains of alum to the 4 lb. loaf. The second analysis was by Dr. Stevenson, who certified that he could not find any alum. Mr. Patteson dismissed the summons, and ordered the Greenwich District Board of Works to pay five guineas, the cost of the second analysis.—Mr. Pook, who had been engaged in other cases in which convictions had taken place, but the fines had been postponed, asked that the summonses might also be dismissed, on the ground that such convictions had taken place on the evidence of the local analyst.—Mr. Patteson said that an error in one analysis was to be taken as an error in the others, and these summonses, as also two others not gone into, were dismissed, with the same conditions as to allowance of costs.

ADULTERATION OF FOOD ACT—PENALTIES.—Representatives of several of the metropolitan district boards and vestries are combining to urge the Government to introduce a clause in the bill to be brought forward to amend the Adulteration of Food, &c., Act, 1872, so as to provide that penalties recovered from persons for adulteration shall go in aid of the expenses of the vestry or district board by whom the proceedings were instituted.

PLOMESGATE UNION—MEDICAL OFFICER OF HEALTH.—The Plomesgate Union Rural Sanitary Authority have declined to appoint a medical officer of health pursuant to the Public Health Act, 1872. The Local Government Board, under these circumstances, have stated that the Board will feel bound to take such legal measures as may be necessary for compelling the authority to appoint such an officer.

SANITARY WORK IN THE HOLBORN DISTRICT.—From the annual report of Dr. Septimus Gibbon, the medical officer of health for the Holborn district, for 1873, it appears that during the year the Artisans' and Labourers' Dwellings Act has been applied to twelve houses, with the result of demolishing four and making eight fit for habitation. In all 1,438 places had been inspected and reported upon—slaughter-houses, cow-yards, and bake-houses visited; 359 sanitary improvements had been required to be done at the hands of owners and the requisitions complied with; 150 houses had been repaired, cleansed, and limewhitened; cesspools had been emptied, twenty-four houses supplied with water for domestic purposes, 103 rooms disinfected after infectious diseases, nineteen illegal underground rooms had been closed, fifteen houses had had their over-crowding diminished, twenty-five houses had had their ventilation improved, and a mass of other work had been done in regard to trapping drains, repaving yards, placing water to closets, cowsheds cleansed and removed, providing, covering, or repairing water receptacles, and the like, which it would be thought the people in their own interest would require without the intervention of an officer. Besides these duties, articles exposed for sale had been seized and destroyed as unfit for human food, and various trade nuisances had been abated.

LONDON HOUSES.—Dr. Corner, medical officer of the hamlet of Mile-end Old Town, reporting on the condition of the dwellings of the poor in the district under his charge, says the relation between houses and the health of

their occupants is admittedly intimate. Nevertheless, houses still continue to be, and are allowed to be, erected with entire disregard to sanitary views. The foundations are unprepared, the ground being well impregnated with the materials for malarious emanations. The superstructure is deposited, or, more technically, 'run up,' and, if guided by any principles at all, they are those most antagonistic to the health and comfort of the future occupants. This applies not only to the dwellings of the poorer classes, but also to those of a more pretentious character. Then the materials are often of a nature and quality which may, in various ways, endanger the health of the occupants. The contents of dustbins are mostly used in the manufacture of bricks, &c. If these contents were composed of ashes only no danger need be feared, but it is a question whether the baking process always destroys any deleterious ingredients. Again, old materials from fever-dens may with impunity be used in the erection of new houses, and thus insure an early outbreak of fever. All these evils are allowed without any attempt at prevention or supervision. No advance has been made in improving the internal structure of moderate-sized houses. There are still the same dark and awkward passages and stairs, smoky chimneys, doors in wrong places, and rheumatic ventilation—in short, everything antithetical to health and comfort.

MISCELLANY.

HIGHER EDUCATION OF WOMEN.—At the University of Bern (Switzerland) the courses of the Faculty of Medicine are at the present time followed by twenty-five ladies as students, among whom are twenty-two Russian ladies, whom the last ukase of the Russian Government forced to quit Zurich, and who have transferred their residence to Bern, in order to continue their studies there. This circumstance has induced the rector of the university to take as the theme of his discourse on the anniversary celebration of the foundation of the University, the higher education of women, and to express his conviction that such instruction is right and necessary. He added that the experience of that University had thus far been altogether favourable. The declaration of the Professors of the University of Zurich, from which the Russian ladies were driven by the Government ukase, is also highly favourable to the ladies; they have denounced the statements in that ukase as altogether unfounded and calumnious, and made solely for political purposes.

A FRENCH VIEW OF MEDICAL PROGRESS IN 1873.—M. P. Garnier writes:—Although the medical year of 1873 has failed to bring forth one of those proud discoveries which make an era—such as that of the circulation of the blood, auscultation, anaesthesia—yet it has not been barren in original views, in important applications, and in researches and work of every kind. Without pretending to estimate from afar the power and value of the scientific movement in foreign countries by the feeble echoes that reach us through their journals, it is certain that France is still the mistress in clinical and therapeutical medicine, which are the essential bases of the art. An analysis of the work of the year proves this.

The pathogeny and etiology of albuminous expectoration which occurs after thoracocentesis, was brought before the Société Médicale des Hôpitaux de Paris. This is a true clinical discovery. Similar accidents observed in Brazil after paracentesis may be compared with it. Another discovery is that of areolar pleurisy, by M. Moutard-Martin. A yellowish gelatinous matter, containing numerous lymphoid cells, found in the peritoneum at the necropsy of a woman, consecutive to a pretended spontaneous rupture of an ovarian cyst, made us compare these facts with the gelatinous disease of the peritoneum, described by M. Péan, in 1871. This new affection of the serous membranes calls for special attention.

The extension of the trophoneurotic etiology to perforating disease of the foot, to sclerema, scleroderma, certain ulcers, to pulmonary apoplexy of the paralysed side, and to many other affections of the muscles, of the articulations, and even of the bones, is so far a French clinical conquest, that we claim it for her.

We may also cite the ambulatory or apyretic form of typhoid fever, pointed out by M. Vallin, in opposition to that absolute law of the Germans, that every disease which, by the evening of the fourth day has not reached 103° Fahr. is not typhoid fever; hysterical anorexia, uræmic encephalopathy of the newly born, bronchial adenopathy, peritonitis, and rheumatismal pleurisy, tracheocele, myelic neuroma, &c. If we compare the reality and clinical value of these new, indigenous, pathological entities with the agoraphobia and rôtheln of the Germans, the anæmic form of fatty heart in young subjects, dysidrosis, gouty iritis, cellulitis of the neck, tetaniform pseudo-paraplegia, neurotic phthisis of foreign origin, it is easily seen that certainty and precision of diagnosis are in our favour. Even chloralium, the paralysis of which had been particularly observed in England in the highest degree, has gained in clearness and precision by the pen of Professor Gubler. We note also the convulsions of sucklings, caused by the alcoholism of their nurses, and epileptiform convulsions, caused by ammoniacal injections, as well as the fresh confirmations of provoked epilepsy. These are clinical observations of far greater importance than the new interpretations of hypertrophic lichen, traumatic herpes, azoturia, anadrosis, diphtheritic buboes, and other vagaries of the imagination and language, which encumber and embarrass science more than they enrich her.

Besides these nosological novelties, no less important therapeutical innovations have been introduced on every side. The hæmostatic method of Esmarch, sprung directly from the elastic suture used in France, England, and Italy for many years, and recently revived in Vienna, promises to render the greatest services to surgery by the various applications that have already been made of it here and there. The prevention of hæmorrhage and even of all loss of blood is so important in operations, that the new process of enucleation of large tumours used by M. Letiévart for the same end equally merits to be noticed. Aspiration comes next, and the extension of its employment to dilatation of the stomach is a fresh proof in favour of its generalisation.

The lengthening of the bone by the irritation of the periosteum is another method which, supported by evident facts, will before long become part of the current practice of surgery.

New medicines have not failed to be brought forward as in preceding years, such as propylamine, trimethylamine, chloralum, and ditaine, none of which have taken hold amongst us. Important observations have been made on current medicines. Chloral has been shown to be antiputrescent in its action by combining with albuminoid matters; hence, its success against phagedæna, eschars, gangrenous wounds, &c. These new properties and its valuable hypnotic action in calming tetaniform and abortive contractions of the uterus, or its painful and irritating contractions during delivery, will considerably increase the use of this agent. The hopes founded on the use of sulphate of quinine as an obstetric agent have, on the contrary, failed; in spite of its evident experimental action on bitches, Professor Chiara has shown that it possesses no positive exciting action on the uterine fibre of the woman. There is, therefore, no danger in administering it as an antiperiodic during pregnancy. This is a new proof that what is true of animals is not always true of man, and *vice versâ*.

The experiments of M. Davaine and others on septicæmia have shown that inoculations which succeed in the rabbit and the guinea-pig are entirely unsuccessful in the larger animals. M. Davaine's conclusion that bacteria form the *corpus delicti* in the transmission, although in hypothetical conformity with the panspermist doctrine of M.

Pasteur is entirely contradicted by the experiments of M. Onimus and M. Colin.

The experiments on the transmission of tuberculosis by the alimentary canal have equally failed to show that animals can in this way transmit their diseases to man.

PROFESSOR ROKITANSKY'S SEVENTIETH BIRTHDAY was celebrated in Vienna on Thursday, the 19th instant, with great *éclat*. The proceedings of the day were commenced with the investiture of Professor Rokitansky, by the Emperor, with the Cross of Commander of the Order of Leopold. At 11 A.M. a public meeting was held in the Academy of Sciences, where an address was delivered by Councillor Langer, professor of human anatomy in the University; after which a bust of Rokitansky was unveiled, and the *Gesängsverein* of the academy then sang an appropriate chorus. Congratulations were then presented to Rokitansky, by deputations from learned bodies, in the following order:—1. The Imperial Academy of Sciences (of which Rokitansky is president); the deputation was headed by the vice-president Ritter von Arneht, and presented an album containing photographs of members of the Academy; 2. The University of Vienna; the deputation was headed by the Rector Magnificus, Professor Vahlen; 3. Burgomaster Felder, on the part of the Municipal Council of Vienna, with the freedom of the city; 4. The Rector of the University of Prague, with the honorary diploma of doctor, and the representatives of the remaining Austro-Hungarian universities in the order of their foundation, viz. Cracow, Pesth, Gratz, Innsbruck, and Klausenburg; 5. The Students of the High Schools of Vienna; 6. The Municipal Council of Gratz, in Styria, with the freedom of the city; 7. The Medical Practitioners in Vienna, headed by their Dean, Councillor Dr. Helm; 8. The Medical Officers of the Army, headed by General Staff-Surgeon Dr. John von Hassinger, with an address; 9. The Supreme Sanitary Council; 10. The Sanitary Council of Lower Austria; 11. The Sanitary Councils of Hungary and Moravia; 12. The Berlin Medical Association; 13. The medical practitioners of Baja, in Hungary; 14. The hospitals, represented by Dr. Hoffmann; 15. The Pathological Society of London, with a diploma; 16. The Imperial Academy of Constantinople; 17. The Medical Association of Vienna; 18. The Psychiatric Association of Vienna; 19. The Imperial and Royal Medical Society of Vienna. At 6 P.M., a banquet took place, at which about 240 guests were present, including the wives of Professor Rokitansky and of his sons. The chair was taken by Prince Joseph Colloredo Mansfeld. Several members of the Austrian Ministry and other public functionaries were present. At 9 o'clock there was a torch-light procession of students, with music.

THE CHOLERA AT MUNICH.—Recent advices from Munich announce that the intensity of the cholera epidemic increases daily in that unfortunate city. The well-to-do population have taken flight in all directions, carrying with them the germs of the disease; and those who are left behind are decimated. The terrified population hardly leave the churches, nothing but bells are heard, and nothing but processions are seen. It is needless to add that business is almost at a stand-still, and that the distress is extreme. During the last week there were 55 cases, of which 25 were fatal. The total number of cases since the reappearance of cholera (Nov. 15), is 2,788 cases, with 1,303 deaths.

SIMILARITY IN TWINS.—Dr. J. F. Bird writes that he has invariably found that when twins are contained in the same sac, and are sustained by the same placenta, they have always had a remarkable resemblance to each other; whilst those contained in different sacs, and sustained by different placentae, are as unlike as children born of the same parents at different periods. His hypothesis is sustained, not only by repeated personal observation, but also by inquiries made of other observers.—*New York Medical Record*, Jan. 15, 1874.

LIST of Naval Medical Candidates who were successful in the Competitive Examinations held in London in August, 1873, and at Netley in February, 1874, after having passed through a course at the Army Medical School at Netley, and who will receive Commissions as Surgeons in the Royal Navy.—

THE NEW MEDICAL BARONET.—Dr. BURROWS, on whom the honour of a baronetcy has been conferred by the Queen at the instance of the outgoing Ministry, has long been designated by the voice of the profession for that distinction. Dr. Burrows graduated as M.D. of Cambridge in 1831, and was a Fellow of Caius College. He was for many years physician to St. Bartholomew's Hospital, of which he is now consulting physician. He has held in succession all the most honourable posts in the profession which are within the reach of a physician; having been President of the General Medical Council, President of the British Medical Association, President of the Royal Medical and Chirurgical Society, and being now President of the Royal College of Physicians. Dr. Burrows is still hearty and vigorous, and his selection for a baronetcy has given general pleasure in the profession, for his life has been blameless, laborious, and useful.

MUSTARD PLASTERS.—It is stated that in making a mustard plaster, no water whatever should be used, but the mustard mixed with the white of an egg; the result will be a plaster which will 'draw' perfectly, but will not produce a blister even upon the skin of an infant, no matter how long it is allowed to remain upon the part.

PROFESSOR KÖLLIKER, of Würzburg, has received an invitation to a professorship in the University of Bonn.

THE Emperor of Austria has conferred the Gold Cross, with the crown, on Dr. Ferdinand Gallasch of Ebensee, in recognition of his long and valuable service as a practitioner of medicine.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO.: London; and through their Agents:—Paris: Mr. G. BOS, SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MARCH 4, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

SANDS ON HÆMORRHAGE FROM THE INTERNAL CAROTID ARTERY SUCCESSFULLY TREATED BY LIGATURE.*

Having occasion to disarticulate the left half of the lower jaw for scirrhus, situated chiefly on the inner aspect of the ramus and body of the bone near the angle, Dr. H. B. Sands, of New York, met with copious arterial hæmorrhage. The hæmorrhage being temporarily checked by pressure with the finger, an inch of the external carotid artery and portions of equal length of the digastric muscle and the hypoglossal nerve were observed running through the tumour, and Dr. Sands thus describes the further proceeding.

These parts were necessarily divided and removed, together with the tumour. The external carotid, together with some smaller arterial vessels, having been tied, I was about to close the wound, when free venous bleeding took place from a small opening that I had accidentally made in the internal jugular vein. After some reflection as to the best course to pursue, I seized the margins of the wound in the vein and applied a lateral ligature, not occluding the calibre of the vessel. The wound was then closed by sutures, except at its middle part, where an opening half an inch long was left for the exit of the ligatures. During the operation, it was noticed that the upper part of the common carotid and the internal carotid artery from its origin to the base of the skull were exposed, and could be seen pulsating at the bottom of the wound.

On the tenth day after the operation, at ten o'clock in the evening, while my partner, Dr. Curtis, was engaged in cleaning the wound, a sudden escape of blood took place both from the external opening and through the mouth. Dr. Curtis at once compressed the common carotid with the left hand, and, ripping open the upper end of the original incision, passed in two fingers of the right hand and made pressure over the line of the internal carotid. The hæmorrhage ceased at once, about two ounces of blood having been lost, whose colour gave no certain indication of the source of the bleeding. Pressure was successfully maintained until my arrival, at the end of about half an hour. It was then found that one of the upper two fingers covered the bleeding point, which was evidently above the carotid bifurcation, and Dr. Curtis was relieved by my pupil, Mr. Shafer. The ligatures were then examined, and that on the internal jugular vein was identified and found to be attached far below the bleeding point. No ligature

could be identified as belonging to the external carotid artery. After looking at the ligatures, I, without giving ether, prolonged the opening in the neck downward along the anterior edge of the sternomastoid muscle, and endeavoured to reach the common carotid high up. Owing to the altered condition of the parts, this proved impracticable; so, having divided the omo-hyoid muscle, I exposed the artery just below it, where the tissues were normal, and passed, without tightening it, a ligature. The common carotid was then compressed between the ligature and the finger, and pressure relaxed upon the bleeding-point. A very vigorous spurt of blood followed, and pressure was resumed.

An examination of the surface immediately above the seat of hæmorrhage revealed a very soft pulsation just beneath the granulations along the line of the internal carotid. The latter vessel I directed Dr. Curtis to dissect while I controlled the bleeding. The internal carotid was exposed by scratching through the condensed tissues with the point of a grooved steel director; a ligature was passed and was immediately tightened, as was just afterward the one encircling the common carotid. I then lifted my finger from the bleeding-point, and no gush followed, but a bleeding continuous in character, and small in amount. This was easily controlled by pressure just below the opening, and for the first time the exact seat and nature of the latter were completely open to inspection. The blood was found to come from a small, circular, clean-cut ulceration in the side of the internal carotid artery, situated an inch below the upper ligature and the same distance above the upper border of the thyroid cartilage. Through this opening, the white and glistening surface of the inner coat of the opposite side of the arterial wall was distinctly visible. After ascertaining the opening to be in the side of the internal carotid, I readily exposed this vessel two or three lines below the opening, and applied a ligature, thus cutting off the source of the trifling hæmorrhage which had persisted after the tightening of the first two ligatures. This hæmorrhage must have been caused by the recurrent circulation through branches springing from the stump of the external carotid. The lower portion of the wound was then closed by a few silk sutures, and the rest lightly filled with dry lint.

The operation, which lasted about two hours, was wonderfully well borne, the patient making no complaint. He lost altogether, both during the operation and the antecedent hæmorrhage, not more than four or five ounces of blood, and the pulse continued firm throughout. Milk and iced brandy were administered through the night, and the patient obtained sleep without anodynes.

The two ligatures on the internal carotid separated on the ninth day, that of the common carotid on the fourteenth day, and that of the internal jugular vein on the seventeenth day after their application. The upper ligature on the internal carotid had in its noose an offensive white slough of the artery three-eighths of an inch long, and another hæmorrhage was feared. None occurred, however, and the patient recovered completely without any further unpleasant symptoms.

Lesions of the internal carotid are usually so rapidly fatal that no opportunity is afforded for surgical treatment. But even when the surgeon interferes success is not generally attainable, and, so far as I have been able to ascertain, there is only one

* *New York Medical Journal.*

other example of recovery recorded besides the one herewith reported. This case occurred in 1807, in the practice of Dr. Twitchell, of Keene, New Hampshire, and in many respects it resembled my own. The hæmorrhage was secondary, and took place ten days after a gun-shot injury, while Dr. Twitchell was in the patient's house. He applied a ligature on the cardiac side of the opening in the wall of the internal carotid, but was obliged to check the recurrent hæmorrhage by means of a graduated compress, as the opening was in that part of the artery which lies just beneath the base of the skull.

From various sources I have collected the following instances of hæmorrhage from the internal carotid. Some were treated and others were not, while all terminated fatally.

1. A hunter received a penetrating bullet-wound of the face. Hæmorrhage occurred on the third day, after the administration of an emetic. Death took place on the fourth day, during an attempt to tie the common carotid. At the necropsy the ball was found lying behind this vessel, opposite the bifurcation. The internal carotid showed a longitudinal rent one-fourth of an inch in length.

2. Abernethy tied the common carotid for hæmorrhage from a wound in the neck inflicted by a cow's horn. The patient died thirty hours after the operation, with symptoms of hemiplegia. At the *post mortem* operation the facial, lingual, superior thyroid, and internal carotid arteries were found torn.

3. Langenbeck tied the common carotid for hæmorrhage from the internal carotid, caused by the ulceration of an epithelial cancer. Death occurred soon after the operation, and an ulcer not larger than the head of a pin was found in the coats of the internal carotid.

4. A. Smith ligated the common carotid for hæmorrhage from the internal carotid, caused by a phagedænic ulcer of the tonsil. The patient died in six hours.

5. In the *Medical and Surgical History of the War of the Rebellion* a case is reported in which the common carotid was tied for hæmorrhage from the internal carotid, caused by a gun-shot wound. The hæmorrhage recurred and carried off the patient.

6. Baizeau tied the common carotid for hæmorrhage from the internal carotid, caused by disease of the ear. The bleeding was not arrested, and proved fatal on the third day. At the necropsy an opening was found in the internal carotid, produced by caries of the walls of the tympanum.

7. Broca performed an operation like the one last described, and with a fatal result, due to hæmorrhage.

8. Billroth, in a case of hæmorrhage from the right ear, due to ulceration of the internal carotid, tied the right common carotid, and a fortnight subsequently the left common carotid. Death from hæmorrhage occurred two days after the last operation.

9. Dupuytren reports the case of a man who received a perforating bullet-wound of the neck at the level of the inferior maxilla. Hæmorrhage, which pressure failed to arrest, occurred on the tenth day, and proved fatal on the twelfth day. At the necropsy, a wound one half an inch in length was discovered in the internal carotid, two inches above its point of origin.

10. Heyfelder relates that a soldier received a penetrating wound on the left side of the neck, and died of hæmorrhage eight hours after the injury. Ice-bags were the only means employed to check

the bleeding. The internal carotid was found to be almost completely divided three and a half lines above its origin.

11. Bécлар states that a travelling charlatan wounded the internal carotid while attempting to excise an enlarged tonsil. The operator fled, and Bécлар was summoned just in time to see the patient die from hæmorrhage. A wound of the internal carotid was found *post mortem*.

In some of the cases above mentioned—namely, those in which the hæmorrhage was due to disease of the petrous bone—the application of a ligature on the distal side of the arterial lesion was impossible; and the case that I have reported is the only one so far as I am aware, in which a lesion of the internal carotid has been treated by the application of a double ligature to the injured vessel, one on the proximal and the other on the distal side of the bleeding-point. The result affords additional evidence of the soundness of the rule laid down by Mr. Guthrie; a rule which is too often neglected, as is shown by the surgical reports of the late civil war, even at the present day. It is not perhaps difficult to explain why a surgical maxim so generally admitted to be binding should be so often disregarded. The application of a double ligature to the bleeding vessel is simple in principle, but generally difficult and sometimes impossible in practice. The deep situation of the bleeding vessel, its relation to other important parts, and, in cases of secondary hæmorrhage, the infiltration of the surrounding textures with inflammatory products, offer serious and sometimes insuperable obstacles to the application of a double ligature near the opening in the arterial walls. In these circumstances the temptation to apply a simple ligature to the main trunk is very great; and experience shows that this operation, either alone, or, as in Dr. Twitchell's case, in conjunction with pressure, may sometimes insure the desired result. Yet success in such an operation can never be expected, and the surgeon should in no case perform it except as a last resort, and after an attempt has been fairly made to apply a double ligature according to the rule admitted by nearly every surgical writer as imperative. In the present case, it is plainly evident, that unless the ligature had been applied above as well as below the bleeding-point, death from hæmorrhage would have rapidly and inevitably followed, as it was noticed that the simple interruption of the circulation through the common carotid produced no appreciable diminution in the violence of the bleeding, which, however, ceased almost entirely when a ligature was applied to the internal carotid beneath the base of the skull. The slight recurrent hæmorrhage still going on was controlled by the third ligature, placed just below the bleeding-point. This ligature I should have applied at first, instead of tying the primitive carotid, had the state of the parts rendered the requisite dissection practicable.

Finally, it may be interesting to note the success which attended the application of a lateral ligature to the internal jugular vein. In spite of the weight of authority in favour of treating wounds of large veins by the use of a double ligature, completely surrounding the vein above and below the bleeding-point, I am strongly inclined, if the wound be small, to trust to a single ligature, applied laterally, so as to include merely the edges of the wound, and not to interrupt the current of blood through the injured vessel. In case the wounds were of large size I

should then regard the complete ligature of the vein as affording the best guarantee of success.

LANKESTER ON THE MANAGEMENT OF INFANTS.

The following 'Plain Rules for the Management of Infants' has been drawn up by Dr. E. Lankester, F.R.S., Medical Officer of Health for St. James's, Westminster, and was issued in the form of a pamphlet by order of the vestry. Instruction has been given for presenting copies to persons registering the birth of children; and copies of the pamphlet may be obtained, for the purposes of distribution, by any parishioner, at the St. James's Vestry Hall, Piccadilly.

Cleanliness.—One of the first things necessary for the health of a child is that it should be kept clean. For this purpose healthy infants should be put into warm water night and morning, care being taken to avoid the extremes of heat and cold. After bathing the body should be cleansed from head to foot with a sponge or flannel with a little soap. The body should then be dried with a warm soft towel. The heat of the water may be gradually lowered as the child grows older. Washing in cold water is not desirable, except in summer, for young children.

The Dress of Children.—Children should be clothed in such a way as not to interfere with the free play of their limbs. They should be clothed warmer in the winter than in the summer, and the common deadly practice of allowing their arms and legs to go bare should be avoided. Every part of the body should be warmly clad, except the head. Woollen clothing is best for the winter, and linen and cotton for the summer.

Fresh Air.—One of the great necessities of life is fresh air. Children should always be placed in bed where fresh air can come to them. It is calculated that three thousand children are suffocated in bed every year in the United Kingdom by the ignorance of their mothers of the necessity of fresh air. Mothers should not fall asleep whilst their children are sucking at the breast, nor should infants be allowed to sleep in bed with their parents. A crib or bassinet is the safest place for a child whilst its parents are in bed and asleep. Children die most in overcrowded rooms. A room should contain 500 cubic feet of air for every man, and woman, and child living in it. In fine weather an infant should be taken out at least twice a day, winter and summer. In winter it should be warmly clothed, and in summer it can hardly be out in the open air too much, except when it is sleeping.

Sleep.—Sleep is very necessary to young infants. They should be laid to sleep at regular intervals, away from light and noise, and not awakened unnecessarily. It is better that children should sleep in a cot than in their mother's or nurse's arms, and in no case should they be rocked to sleep in a cradle. No kind of cordial, spirits, syrups, sleeping drops, or other remedies should be given by the mother or nurse, to make the child sleep. If the child is sleepless it is ill, and medical advice should be obtained.

Food.—One of the most frequent causes of the early death of young children is improper feeding. The proper food of children is breast-milk. When the mother and child are both healthy, no other food is required for the first six months. When the child is first born no other food is required, and the prac-

tice of giving gruel, butter, honey, and castor-oil to new-born babes, is pernicious and destructive to their health. When the mother has a deficiency of milk, cow's milk is the best substitute. It should be given with a third of warm water and a little sugar. For the first six weeks the child should be suckled every two hours in the day and every three or four hours at night. Gradually as it gets older the intervals of feeding may be prolonged. Children should not be fed to keep them quiet, but at regular intervals. Mothers should never fall asleep when suckling their babes. This is one of the most frequent causes of suffocation in bed.

Nursing.—A mother whilst nursing ought to live generously and well, but not carelessly or grossly. She may take porter or ale, but certainly not more than a pint of either a day. On no account should any kind of spirits be taken. When nursing, a mother suffers from giddiness, palpitations, shortness of breath, or night sweats, she should consult a medical man as to the propriety of weaning the child. Before the child is six months old, if the mother is weak, it may be fed on cow's milk alternately with its mother's milk. This is better than bringing the child up by hand alone.

Weaning.—A child should not be weaned suddenly, but by degrees, and ought not to have the breast after the ninth month. When the child has cut its front teeth it may have some light food, such as bread, baked flour, or milk biscuits added to its milk, or it may have 'Liebig's Infant Food,' which is sold in the shops. It may also have, once a day, meat-broth, or beef-tea, with bread or biscuits soaked in it; or it may have the yolk of an egg, lightly boiled. When it is a year and a half old it may have some fine chopped meat, but milk should form the principal part of its food. Such food as solid meat and potatoes, fat pork and fish, which form the food of grown-up people, should on no account be given to children.

Hand Feeding.—When it is impossible for a mother to give milk to her child, or to procure a wet nurse, the child must be fed by hand. In this case it should be remembered that *milk*, and *milk* only, should be used for feeding the child. Cow's milk, diluted with one-third water, and sweetened with a little sugar, is the best form. The milk thus prepared should be given from a feeding-bottle, which should be emptied after every meal, and thoroughly cleansed with hot water, and the cork and teats kept in water when not in use. When the bottle smells sour, it ought not to be used. The child should be fed regularly with its bottle, and by no means to have it merely to keep it quiet.

Most of the deaths from hand feeding, under six months old, arise from the use of *corn-flour*, *arrow-root*, *baked flour*, and *other kinds of starchy food*, which contain no nutritious qualities, and can never be used as substitutes for milk without endangering the lives of the children who are stuffed with them. When milk cannot be obtained pure, or is open to the suspicion of adulteration with water, then what is known as 'Condensed Milk' may be used with advantage.

PROFESSOR KÖLLIKER has declined the invitation to a chair in the University of Bonn, which was lately offered to him.

DURING the last fortnight twenty sums of 1,000*l.* each have been anonymously presented to metropolitan charities.

MEDICINE.

THE DIAGNOSTIC LAWS OF THE LOCALISATION OF CHRONIC DISEASES OF THE NERVOUS SYSTEM. BY DR. M. BENEDIKT, PROFESSOR IN THE UNIVERSITY OF VIENNA.*

(Concluded from page 114.)

After we have explained what symptoms of central origin have a determinate localisation, and of what kind this localisation is, the importance of the diffusion-law becomes clear to us. Through the whole history of the pathology of the nervous system, from the days of Bell and Romberg, the tendency has been to concentrate in one focus all the aggregates of symptoms in special cases and in certain individual forms of disease. I call to mind only the endeavour of Remak, to localise the different forms of tabes according to their complications.

Still more striking is the question of paralytic dementia. While Meynert was obliged, on account of the preponderance of atrophy of the frontal lobe, to deduce the symptoms of paralytic dementia from disease of this part, Westphal, on the contrary, saw the most essential anatomical precursor of the disease in the changes in the spinal cord. If we analyse the phenomena of paralytic dementia according to the diffusion-law, we shall neither localise it in the frontal lobes with the first author, nor endeavour with the second to connect it with the cauda equina; but we shall first of all determine what symptoms can be localised with accuracy, and thence arrive at the conclusion that paralytic dementia is a disease of diffuse character, extending over the whole of the central nervous system. We shall localise tabetic phenomena in the posterior columns of the spinal cord; alalia, dysphagia, and, in general, the signs of progressive paralysis of the cerebral nerves, in the nuclear region of the cerebral peduncles; hemiplegia without convulsions in the central ganglia or in the cerebral peduncles; hemiplegia with convulsions, or simple convulsions, in the cerebral hemispheres; disturbances of the motor stimulus in the frontal lobes; and certain irregular disturbances of the character described by Hitzig and Fritsch, also in the anterior lobes.

There are also numerous symptoms in paralytic dementia, the localisation of which is for the present impossible, or at least does not rest on a secure basis. To these belong, for instance, the motor disturbances of uncertain character, as when, for example, the patient can walk very well under an impulse, but not spontaneously. This phenomenon is manifestly an outcome of destruction of the innervation-energy of the centres of volition. Further, sufficiently accurate localisation is impossible in regard to the hastiness and the spastic twitchings observed in the movements in many cases of mental disease. Many of these disturbances must be ascribed to disease of the central ganglia on the one hand, and of the anterior lobes on the other. I deduced this several years ago (see my 'Neuropathological Observations in Mental Disease,' *Archiv der Heilkunde*, vol. viii.), before the valuable labours of the authors in Griesinger and Westphal's *Archives* appeared, and a special

pathological anatomy was created for dementia. Each new research confirms these views (see Lubimoff, Magnan, Mierzejewsky, *Archives de Physiologie*, 1873).

The diffusion-law affords us extraordinary aid in the so-called *sclérose en plaques*. The endeavour has been made to regard a certain aggregate of symptoms as connected with this disease; but each case has brought new complications. The reason is obvious: the aggregate of symptoms does not depend on the special form of invasion of the disease, but on the foci which are attacked; on the other hand, it is clear that there is a certain law of diffusion, in virtue of which disease passes on from one part to another, and that thus definite individual aggregate of symptoms are the result of diffuse central neuritis in its various forms.

It is an undoubted fact, which has been established in recent times, that, by our way of making and studying preparations, very many foci of disease are overlooked, and that hence great confusion is produced by explaining all the symptoms by the appearances actually found. By following the diffusion-law, it would be difficult to fall into such errors. For instance, in disease of the spinal cord attended with disturbance of speech, we could not be satisfied with observing the condition of the cord, but would make a microscopic examination of the hypoglossal nerve and its nuclei; and the same would be done in cases of alalia accompanying mental disease.

We know in the present day that it is an error to speak of *sclérose en plaques*, since it has been established by Bourneville's researches that the disease is not limited to foci, but that even the apparently healthy interstitial parts are diseased. We have in reality to deal with a diffuse neuritis, which derives its character, at least so far as regards the spinal symptoms, from a combination of disease of the anterior and lateral columns. The expression *sclérose en plaques* may be retained for clinical purposes; or it may be known as Charcot's type of diffuse central neuritis.

To diffuse neuritis belong also the ascending and descending forms of dementia, the combination of tabes ascendens with dementia (Joffe and Westphal), the combination of glosso-labio-pharyngeal paralysis with progressive muscular atrophy and paraplegia of the arms (Wachsmuth), the combination of general progressive muscular atrophy with disease of the nuclear region of the cerebral nerves without atrophy, the cerebral *sclérose en plaques* (Valentin), &c.

To the aggregate of symptoms which appear in the course of general neuroses, especially hysteria and dementia, belongs also Graves's or Basedow's disease, which very probably is to be localised in the transitional region between the spinal cord and the medulla oblongata.

It would be of great importance to know the law by which central neuritis is spread. Much may depend on the distribution of the vessels; and Duret's article on the distribution of the blood-vessels in the medulla oblongata (*Archives de Physiologie*, 1871) gives interesting information. The nucleus of the question, however, seems to me to lie altogether elsewhere. But I will not make any assertion until material is more abundant.

In the spinal cord, we can say from the researches that have been made up to the present time, that the prevalent tendency of disease is to extend upwards and outwards, while extension inwards is rare, at least in the chronic progressive forms of disease.

I will here make a final remark. Diffuse central

* *Allgemeine Wiener Medizinische Zeitung*, nos. 1, 2, 3, 1874. From an *Introduction to the Pathology of the Nervous System and to Electro-Therapeutics*, now in the press.

neuritis can very rarely be confounded with diffuse neoplasms; the local spread of neoplasms follows another law than that of chronic inflammation. A neoplasm, for instance, does not produce pure symptoms of tabes. But, from my own observations and the impressions made on me by the literature of the subject, it seems to me that a neoplasm may produce diffuse central neuritis at distant points, just as a focal (*herdweise*) neuritis may; so that the existence of a new growth cannot be absolutely excluded by the diagnosis of a diffused process of disease, even separated by healthy portions.

The importance of the diffusion-law not only in a diagnostic but in a therapeutic point of view, will be apparent from the following consideration. Chronic nervous diseases frequently present cerebral and spinal symptoms, each of which will have to be treated *in loco morbi*. In most cases with cerebral symptoms, for instance, all the manifestations are referred to an intracranial process, and the condition of the spine is overlooked so far as treatment is concerned. On the other hand, it seems an extraordinary paradox that psychical symptoms, and also amblyopia and dumbness, receive benefit from galvanisation along the spinal column. If we reflect, that in the progressively ascending form of paralytic dementia the disease may pass on from the cervical enlargement of the cord, or from the cerebral peduncles to the hemispheres, and this seems quite determined in the case of neuritis of the optic and auditory nerves, we shall say that there must be an irritation or paralysis within (for instance) the cervical enlargement, which causes the disease to advance: and it may be assumed that the tranquillising or stimulating effect of the current on the cervical enlargement may bring the secondary symptoms in a distant part to a standstill or cause them to recede. There is no doubt that, with regard to these symptoms, the law of diffusion (not to be confounded with the diffusion-law) has an anatomical foundation and a reflex influence on the vaso-motor nerves—relations which are yet for the most part unknown to us.

It is a very interesting fact, that in chronic inflammation of the anterior half of the spinal cord the process does not pass on to the cerebral nerves; and if this appear to take place in exceptional cases, it is because the posterior part of the cord is involved, although the symptoms of disease of this part are forced into the background by those of the disease of the anterior half.

MULREANY ON THE CONSTITUTIONAL RELATIONS OF SECOND DENTITION.—Dr. Joseph Mulreany (*New York Medical Journal*, January, 1874) records a number of cases occurring in his practice, and illustrating some practical points connected with the protrusion or cutting of the permanent teeth, especially the first four molars and the four wisdom or third molars. He believes that the physiological irritation of a new tooth cutting through the gum is the direct, though frequently unsuspected, cause of many diseases, both of childhood and maturity, and that the results of treatment demonstrate conclusively that such is the case. He says that every case of true hip-joint disease he has met with began between the fifth and seventh years, or it might be a few months earlier; and also that whatever mischief occurred to the joints took place during the cutting of the first four permanent molars, and that, after they

had come fairly through, the process of reparation fairly commenced. His illustrations are numerous, the more important ones being as follows.

Case I. Miss W., when a child of between five and six years, suffered from morbus coxarius. The first indications of the joint-disease were lameness and pain when the head of the femur was strongly pressed against the acetabulum. In process of time the usual symptoms of pain in the knee, flattening of the hip, and shortening of the limb took place, but all in a mild form, and all subsided at the end of her sixth year, coincidentally with the complete protrusion of her first four molar teeth, leaving her slightly lame for life. She was a member of a family of a highly scrofulous diathesis.

Case II.—Margaret McC., aged six and a-half years, had had pain in the left hip-joint and knee for over a year, and was slightly lame; the hip was flattened; the right upper molar was not yet protruded. The gum was well scarified, and she was ordered iodide of iron with senna as an aperient—the gum to be scarified once a week until the tooth came fairly through. In a month she was greatly improved.

Case III.—C. D., aged twenty months, had enlarged and suppurating cervical glands, but was in good condition. About the twenty-fourth month he had cut all his deciduous teeth, and every bad symptom disappeared. In his fifth year, he was suddenly seized with pains in his left hip. He was ordered an effervescing mixture containing iron and iodide of potassium, and a small blister was applied from time to time over the hip-joint. The gums were not scarified, owing to the violence of the patient. This condition continued for a year and a half; sometimes he could walk without the aid of a crutch, but invariably, when he had a teething spell, he was forced to crawl about on all-fours. At this time a surgeon, who was called in consultation, diagnosed such an amount of disease as to warrant immediate resection of the hip-joint, though Dr. Mulreany was convinced that it was a case of morbus coxarius brought into action by dental irritation. Amputation of the head of the femur was attempted, but a deep and ample incision down to the capsular ligament assured the operator that the joint was too sound to justify him in cutting into it. The operation was abandoned; but the final issue of the case is not stated.

Case IV.—A boy, aged six years, was seen in consultation. His physician stated that for six weeks the boy had had a kind of remittent fever, worse at night, with obstinate constipation. On examination, it was found that the first four molars were pressing against the gums, causing much tension, and that there had been epistaxis. A few days later, the child growing worse, the gums were scarified, a laxative mixture was given, and in two days the attack was concluded. An important medico-legal point sometimes arises between the eighth and fifteenth year, the inflamed condition of the gums over the bicuspsids often giving rise to a purulent discharge from the vagina. Too often such discharges have been received as testimony of rape.

Of the phenomena associated with dentition between the seventh and fifteenth year, scrofula of the bones, nocturnal incontinence of urine, chorea, and heart-affections are the most common.

The following cases have a bearing on the cutting of the wisdom-teeth.

Case VII.—Mr. V. aged twenty-three, was subject to violent bilious attacks, low-spirited, sleepless,

constipated; he had frequent epistaxis and pain in the articulations of the lower jaw. None of the wisdom-teeth were through. His gums were scarified, and he was ordered to do the same frequently, and to take a little tincture of iron, and an infusion of senna. He was cured.

Case VIII.—Miss A. D., aged eighteen, tall, fair, anæmic, had a cardiac bruit, violent headaches, profuse epistaxis, and irregular menstruation; the wisdom-teeth were not quite through. Her gums were thoroughly scarified frequently, and quinia and tincture of iron, with senna as an aperient, were given. She recovered.

Case IX.—Miss B., aged twenty, had profuse epistaxis, preceded by jaw-ache, approaching phthisis of the right lung, quick pulse, loud anæmic cardiac bruit, amenorrhœa, frequent micturition, and constipation. The wisdom-teeth had not shown themselves. Her gums were scarified, and she was ordered quinia, iodide of iron, and tincture of digitalis.

Case X.—Miss S., aged seventeen, was pale and exsanguine, and had palpitations of the heart, headaches, constipated bowels, menorrhagia, coated tongue, and a chlorotic bruit. She had lost great quantities of blood, owing to nervous obstruction at the centre of the circulation, caused by dental irritation from the wisdom-teeth acting directly on the heart. Scarifications, iron, and digitalis effected a speedy and perfect cure.

Case XI.—Mrs. J. M. S., aged nineteen, had been married six months, during which time she had had a coloured discharge from the vagina. None of the wisdom-teeth were present. Scarifications and tincture of iron gave the happiest results.

Dr. Mulreany proceeds to state that dental irritation may be the cause of dropsical effusions, both in the chest and in the abdomen, of heart-affections, of hysterical troubles of the joints, of masturbation, and of sterility and miscarriage, and gives cases in support of his views; but he asks that the physiological irritation of which he speaks shall not be confounded with the pathological irritation of an old, decayed, and carious tooth producing periostitis and gum-boil.

FRÄNKEL ON HÆMORRHAGIC LARYNGITIS.—Dr. B. Fränkel gives the history of an interesting case of hæmorrhagic laryngitis (*Berliner Klinische Wochenschrift*, no. 2, 1874). A married woman aged twenty-eight came under treatment on April 26, on account of shortness of breath, hoarseness, and blood-spitting. Her health had generally been good. From her youth she had been subject to frequent epistaxis, especially after violently blowing the nose, but the bleeding had never been copious. Accidental wounds had never bled freely, and no member of her family had shown a hæmorrhagic tendency. The patient was in the ninth month of her fourth pregnancy. During her last two pregnancies she had often had cough and hoarseness, but she had not before suffered from shortness of breath or hæmoptysis. During her present pregnancy, she had had frequent morning sickness. A fortnight before she came under observation, hoarseness came on. Ten days later, dryness of the throat and dyspnoea, and three or four days since, blood-spitting, commenced. There was loud stridor on respiration. The laryngoscope showed the mucous membrane of the larynx universally red and swollen. The colour was not uniform—some parts appearing bright red, others

dark red, and others again nearly black. The vocal cords at first appeared of dark colour, but after the expectoration of some dark clotted blood the cords appeared of bright red colour, and covered with fluid blood. The interarytænoid fold was much swollen. The mucous membrane of the pharynx was slightly red, but scarcely at all swollen. The heart and lung sounds were quite normal. The patient stated that from time to time she had attacks of dyspnoea, with stridor, which ceased after the expulsion of clots of blood.

These attacks were especially frequent during the night. On a subsequent visit, Dr. Fränkel observed the sequence of the phenomena. An attack of dyspnoea, with stridor, ceased with the expulsion of coagula from the larynx. During the stage of dyspnoea and stridor the vocal cords and the interarytænoid fold appeared almost black, and the margin of the glottis was rendered uneven by small reddish black projections, while the interarytænoid fold was covered by bright red blood. A moistened brush was introduced into the larynx, and the patient coughed up some blood-clots, whereupon the breathing became more free, and the dark swellings had disappeared. The mucous membrane of the larynx and that of the trachea, where it was visible, then appeared intensely red and injected. By the aid of the mirror the whole process of capillary submucous hæmorrhage, transudation, and clotting of blood on the surface of the larynx could be seen. When dyspnoea and stridor passed off the voice remained hoarse, and the cough had a husky sound. The larynx was touched with a solution of nitrate of silver (1 part in 15). The bleeding continued to recur more or less frequently and copiously for about three weeks. On some days the dyspnoea, stridor, and blood-spitting, recurred about every half-hour; on one occasion half a cupfull, and on another a cupfull of blood was coughed up. On May 24 she gave birth to a healthy boy, and from that time there was no return of the bleeding.

When last seen, on September 23, she was nursing her fourth child, and appeared in perfect health. The voice was feeble, but not hoarse. There was some swelling of the interarytænoid fold, and the vocal cords were slightly thickened, red, and injected. A most careful examination detected nothing wrong in the lungs or in the heart.

In this case, then, by direct laryngoscopic observation the existence of hæmorrhagic laryngitis and tracheitis was ascertained. The same pathological condition may have extended to the mucous membrane of the bronchi, but of this there was no evidence. It is suggested by the author that the frequent vomiting during the later months of pregnancy may have increased the congestion and determined the hæmorrhagic character of the laryngitis.

GEORGE JOHNSON, M.D.

DISEASES OF CHILDREN.

GALLASCH ON A RARE KIND OF LEUCÆMIA IN CHILDHOOD.—Dr. F. Gallasch (*Fahrbuch für Kinderheilkunde*, Dec. 15, 1873) reports a case occurring in a child four and a half years old. The parents were healthy; there was no taint of syphilis. The child had been subject to bronchial catarrh with occasional swellings of the glands of the neck. There had been no bleeding at the nose. It never had the usual children's complaints. Before its admission into the hospital it had suffered from an asthmatical cough

for the last six weeks. There had been no fever nor sickness. The child had lost flesh very sensibly during the last fourteen days, becoming pale and bloodless. After a stay of three months and a half in the hospital it died comatose. In the *post mortem* examination all the lymphatic glands were found much enlarged, also the liver, spleen, Peyer's patches, and solitary glands. The kidneys were pale, of normal size. The testicles and lachrymal glands were enlarged, especially the latter. Microscopical examination of the testicles and lachrymal glands showed excessive lymphoid infiltration into the surrounding areolar tissue, compressing and diminishing the gland substance. The same lymphoid infiltration was found in the other glands, showing that the progress of the disease was the same in all the structures.

PATHOLOGY.

MENZEL ON SPONTANEOUS STRANGULATION OF THE FINGERS.—Dr. A. Menzel, last year, observed the following conditions in a woman aged forty-four (*Gazzetta Medica Italiana-Lombardia*, no. 31, 1873). The right middle finger, at the middle of the first phalanx, was suddenly contracted to a short pedicle, from which hung a round movable swelling as large as a hen's egg. The pedicle and tumour were covered by skin, the epidermis of which seemed thickened. The surface of the swelling was smooth, but less so near the pedicle, where the epidermis was wrinkled, of pasty consistence, and painful on pressure, although insensible to the prick of a needle. The part was often the seat of spontaneous and very severe pain. The right index finger presented, at the middle of the second phalanx, a deep furrow on the ulnar and dorsal aspects, less distinct on the palmar, and scarcely perceptible on the radial aspect. The phalanges were movable. The nail was claw-shaped. The right thumb was normal, and the fourth and fifth fingers nearly so. The left thumb and index finger were complete; the other fingers were wanting. The left foot was slightly in a state of varus; the toes were adherent to each other. The great and second toes were connected with the foot only by the plantar skin, being divided above by a deep furrow. There were no nails on the first, second, or third toes. The toes of the right foot were without nails; the great and second toes were united at the first phalanx. All these defects were congenital.

The tumour on the right middle finger was removed by scissors; there was no hæmorrhage. On cutting through it and its pedicle, the surface of the incision had a soft, moist yellow appearance; the peduncle was pale and firm, and passed into the tumour, ending at its centre in a bony knob. On microscopic examination, the epidermis was found to be thickened, and its deeper layer exclusively formed of spinous cells. The papillæ were regularly arranged; they were long, often bifid or trifid. The sudoriparous glands were well formed, but their ducts were straight in-

stead of spiral. The remainder of the swelling had the appearance of subcutaneous tissue. The walls of the vessels were thickened; and the bone was tolerably porous. On longitudinal section of the pedicle, it was found to consist of connective tissue, without any bone; the fibres running in a direction parallel to the axis of the pedicle. The vessels were arranged as in bone. On the cutaneous surface of the pedicle, along with dwarf papillæ, there were large strong ones, alternating with others which were very long and slender, and bifid or trifid. There were irregular interpapillary fossæ.

Dr. Menzel remarks that the possible causes of spontaneous strangulation of the fingers are twofold; either the connective tissue contracts like a cicatricial ring, dragging the cutis inwards, or the epithelium itself forms a furrow in the tissues. The condition of the parts which he found on section, and the congenital nature of the deformity, lead him to adopt the idea of an epithelial furrowing, having its normal counterpart in the division of the hand into four fingers by the formation of four sulci in the seventh week of foetal life. He has not been able to find a similar case, except one recorded by Dr. Wucherer in Virchow's *Archiv*, vol. lvi.

[Mr. Erichsen, in his *Science and Art of Surgery* (sixth edition, vol. ii. p. 298), gives two drawings of a case of this kind which came under his observation in a child some years ago. Two of the fingers were marked by deep transverse sulci; others were shortened and terminated in rounded nodules, with a narrow pedicle connecting them with the proximal phalanx.—*Rep.*]

ANATOMY AND PHYSIOLOGY.

TOMSA ON THE STRUCTURE OF THE SKIN.—Professor Tomsa of Kiev in Russia publishes in the *Archiv für Dermatologie und Syphilis* (1873, i.) a long and elaborate paper on various points in the anatomy and physiology of the skin. Starting from the zones and territories described by Langer in his paper read before the Vienna Academy of Sciences (*Sitzungsbericht der k. k. Akad.*, vols. xlv. and xlv.), the author describes the felted arrangement of the fibrillæ in the papillary layer of the corium, and the looser texture of the deeper or reticular layer, where the great bundles of fibrous tissue form rhombic and polygonal spaces by their intersection, which make on section a kind of lattice-work. There is also a distinct, though not uniform, arrangement of this tissue in successive layers, parallel to the surface. All this structure the author finds equally in the zones, which more or less perfectly encircle the limbs and trunk, and in the spaces between them. He then shows the arrangement of the hair-follicles, which are connected, not by their blind extremities, but by their edges, with four bundles of fibres running obliquely up from the reticular layer of cutis, and crossing each other obliquely before they expand in the papillary layer so as to surround the mouth of the follicle. This applies chiefly to the white fibres, as

seen in tanned specimens of human skin. The elastic tissue is more irregularly disposed, while the inter-fibrillar cement (*Kittsubstanz*) pervades all parts alike.

The author does not find any continuous layer of endothelium lining the spaces into which the cutaneous lymphatics open.

The arrangement of the muscles of the skin is next described with great minuteness, and illustrated by figures of a mechanical model constructed for the purpose.

The second part of this paper deals with the blood-vessels of the integuments. The plan employed by the author was to inject first the veins and then the arteries with different coloured fluids, so that the place of meeting in the capillaries could be afterwards recognised. Professor Ludwig's apparatus was used; the injections consisted of size, coloured with solution of Berlin blue, watery solution of hydrated oxide of iron, dialysed and afterwards concentrated by evaporation, or ferrocyanide of copper dissolved with oxalate of ammonia. Carmine injections did not succeed; the colour stained the surrounding tissues, in spite of all precautions. Pieces of skin in which the injection had run well, from the face, arm, foot, hand, scrotum, trunk, &c., were hardened in alcohol: sections were made in various directions, and cleared with acetic acid and glycerine, or with turpentine.

The most important results of these observations, which are illustrated by numerous well-executed coloured drawings, are as follows.

1. There is no direct communication between the cutaneous arteries and veins, as supposed by M. Sucquet: the capillary network is complete throughout.

2. There is no special capillary system for the fibrous and elastic tissue of the skin. Fine injections show that the capillaries are arranged as follows: (*a*) in the papillæ, where their function is supposed by the author to be the formation of epidermis; (*b*) around the convoluted part of the sweat-glands, and the sacs of the sebaceous and hair-follicles; (*c*) among the arrectores pilorum and the muscular fibres of the dartos; (*d*) surrounding the nerve-fibres and the minute ganglioniform enlargements which have been described by the author; (*e*) forming a somewhat loose and scanty network around the arteries—external vasa vasorum; (*f*) supplying the lobules of adipose tissue. Two points in the description of these capillary systems are worthy of special notice: one, that the sweat-glands are quite unconnected in their blood-supply with the papillæ, so that there is no second capillary network in the skin, as in the kidney; the other, that the special capillaries of the adipose tissue can be recognised in the foetal integument before any fat-cells have been formed.

3. Three vascular layers may be distinguished in the human skin: a deep one, supplying the subcutaneous fat and deepest part of the corium, a mid-layer for the sweat-glands, and a superficial papillary network. The last discharges its blood into a venous plexus, which is almost erectile in character. The three corresponding sets of veins finally open into common collecting branches, visible to the naked eye.

4. The author confirms the observations of those histologists who have frequently met with papillæ which are at once nervous and vascular.

P. H. PYE-SMITH, M.D.

MALASSEZ ON THE NUMERATION OF THE RED CORPUSCLES IN BLOOD.—Dr. Malassez has recently published a memoir on this subject in Paris. After analysing carefully the methods of MM. Vierordt, Cramer, Mantegazza, and Potain, he describes a method devised by himself. It consists, briefly, in making, with a pipette of particular form, a determinate mixture of blood with a liquid, which produces a spreading out of the blood, without alteration of the corpuscles. The liquid employed has, for formula:—

Solution of gum arabic, giving a density of 1.020 . . . 1 vol.
Solution of sulphate of soda and chloride of sodium, in equal parts, giving also a density of 1.020 . . . 3 vol.
To which is often added—

Carbonate of potash or of soda . . . 1 drop in 15 grains of serum.

Instead of spreading the mixture in lines, like M. Vierordt, or depositing it in droplets, like M. Potain, Dr. Malassez introduces it into a very fine capillary tube, which one may examine with a microscope, as one examines the vessels in a frog's foot. Then, counting the corpuscles comprised in a certain length of tube (the volume corresponding to this length being determined), one may, by easy calculation, infer the number of corpuscles per cubic millimetre.

A micrometric quadrilled ocular, the quadrilled part of which does not occupy the whole field, and has a square form, enables the observer to count the corpuscles without difficulty.

Dr. Malassez describes a number of physiological and chemical researches made with the aid of this process. The following are some of his principal conclusions.

'The globular richness of the blood, or the number of red corpuscles per cubic millimetre, is extremely variable in the different parts of the circulatory system.

'The variations have their beginning (*point-de-part*) in the capillaries, and perhaps, also, in the small arterioles and venules. They are different in direction and intensity according to the tissues and the organs, and according to the functional state of these.

'The diminution of globular richness is due either to the destruction of corpuscles (liver?) = *real diminution*; or to the absorption of liquids producing dilution of blood (intestine during digestion) = *apparent diminution*.

'The increase of the globular richness is due either to the formation of corpuscles (spleen?) = *real increase*; or to exosmosis of a certain quantity of the liquid part of the blood, which is then either lost by evaporation, or employed in secretions, or taken up by the lymphatics (skin, muscles, submaxillary glands, kidneys) = *apparent increase*.

'Such diminution and increase are in direct proportion to the intensity of the causes indicated, and in inverse proportion to the quantities of blood which pass in the capillaries, and on which said causes act. It is thus that the blood is the less concentrated in a gland the more the latter secretes.

'The variations found in the large vessels appear to be secondary. Other things being equal, they are nil, or little marked in the arterial system. They are, on the contrary, very well marked in the venous system. This difference results from the fact, that the arterial blood proceeds from a single tissue, while the venous blood is formed by the mixture of bloods coming from very different sources. We cannot, then, (as has often been attempted by observers), seek to

compare, in a general manner, the globular richness of arterial blood with that of venous blood.

'These local variations appear on the whole to compensate each other. I have been able to assure myself, by a certain number of experiments (which I hope to publish shortly), that under the influence of certain circumstances, the general globular richness may also present variations, and that, in the actual conditions of life, these variations oscillate about a certain state of normal equilibrium to which they incessantly tend to return.

'In most cases, the figures which I have given in this work represent, exactly enough, the state of the blood, and the intensity of local variations of globular richness. But in others, which I have specially indicated, the results have been tainted with error, not because the method of numeration employed was less good than another, but because the operations to which it was necessary to subject the animals were apt to cause serious perturbation in the phenomena which I sought to study.'

ALEX. B. MACDOWALL.

DITTMAR ON THE VASO-MOTOR CENTRE IN THE MEDULLA.—Owsjannikow placed the under limit of the vaso-motor area in the rabbit about 4 millimètres ('15 inch) from the calamus scriptorius, the upper limit 4 millimètres higher, 1·2 millimètres below the corpora quadrigemina. C. Dittmar (*Berichte der kön.-sächs. Gesellschaft der Wissenschaften, Math.-phys. Classe*, 1873), in order to avoid the uncertainty of making the sections of the medulla with the free hand, as performed by Owsjannikow, has invented an apparatus for holding a small knife, which can be moved in any direction, and for any distance, by means of a finely graduated screw. He also laid the spinal canal more freely open, in order to avoid the accumulation of blood in the sac of the dura mater, as this has been shown to present a reflex action from reaching the vaso-motor nerves. Any bleeding from the bone was easily arrested by the application of small pieces of paper which had been dipped in tincture of iron and then dried. The blood-pressure was measured in the carotid.

The author confirms in the main the results of Owsjannikow, and finds that in the rabbit the lower limit of the vaso-motor area lies about 3 millimètres above the point of the calamus scriptorius, 1 to 1½ millimètres ('04 to '06 inch) below the lower margin of the tuberculum laterale. The upper limit lies in the neighbourhood of the fovea anterior, about the upper margin of the corpus trapezoides. Following the indications given by the experiments of Miescher and Nawrocki, the author found that sections of the anterior and posterior columns, as well as the gray substance of the same, within the third cervical vertebra, did not alter the reflex increase of blood-pressure on stimulation of the sciatic nerve. It, therefore, follows that not only the centripetal fibres (Nawrocki) of the sciatic nerve whose stimulation produces the reflex contractions of the vessels, but also the vaso-motor nerves, run in the lateral columns of the spinal cord. The remainder of the anterior column, pyramids (lying towards the middle line), and the posterior part of the remainder of the lateral column, can be destroyed without materially influencing the reflex vaso-motor activity. There only remains, therefore, on each side, a small prismatic space within the vaso-motor area, whose injury disturbs or causes each reflex to cease. It forms the anterior part of the lateral column.

SURGERY.

PORTA AND VALERANI ON THE RADICAL CURE OF VARIX BY THE INJECTION OF HYDRATE OF CHLORAL.—Professor Luigi Porta, in an article communicated to the Royal Lombardian Institute, and quoted in the *Gazzetta delle Cliniche* (no. 1, 1874) gives an account of the clinical observations which he has made on the coagulant property of hydrate of chloral, and especially of its use in the treatment of varix.

He reports fifteen cases of varix of the leg treated successfully by the subcutaneous injection of hydrate of chloral, beginning with a gramme, and then reducing the dose to a half or a third of a gramme. The coagula are formed at once, and the patient is confined for a few days to bed, to obviate the risk of phlebitis. The coagula ultimately are absorbed, and the veins become atrophied, or remain pervious, though not varicose.

The accidents which may occur are the following. The thrombus may soften; but this only impedes the cure for a time. Phlebitis may occur; but it is slight, and disappears in a few days. Very limited supuration may take place; it does not delay the cure, and perhaps depends on the escape of a small quantity of the chloral into the connective tissue. This may be prevented by drawing up the piston before withdrawing the needle. Circumscribed sloughing of small portions of the skin has been observed in old subjects, probably also from escape of the chloral into the connective tissue. Professor Porta thinks it probable that this mode of treatment will be found applicable also to varicocele (of which he has had a successful case) of various subcutaneous nævi, aneurismal varix, and hæmorrhoids.

Dr. Valerani, writing on this subject in the *Annali Universali di Medicina* for December 1873 (*Gazzetta delle Cliniche*, no. 5, 1874) says that any new method tried for the cure of varix should be free from danger either immediate or remote, easy of application, and fairly constant in result. All these conditions are present in the treatment proposed by Porta.

In order to explain the *modus operandi* of this treatment, Dr. Valerani makes some observations on the venous circulation in the lower limbs. Until within the last few years, he says, it has been believed that the subcutaneous venous system of the lower limb is complementary to the deep venous circulation of the limb; that is to say, that the saphenous veins are destined to receive the reflux blood from the deep veins when the circulation in these is obstructed by muscular contraction or by other causes. The error of this opinion, however, has been demonstrated beyond doubt by Verneuil, Le Dentu, and more recently by Giacomini. On examining the large anastomoses between the superficial and deep veins, it is always found that the valves have their concavity directed inwards; that is, they are so dispersed as to allow the blood to flow from the superficial to the deep veins, but not in the opposite direction. The reflux from the deep to the superficial veins is only possible when the valves are imperfect.

Varix of the subcutaneous veins is then a consequence of dilatation of the deep veins. The deduction from this is, that a fibrinous coagulum should be formed at the point where a valve exists in the normal state, so as to take its place, and prevent the reflux of blood from the deep to the superficial veins.

Professor Porta, not having taken into consideration the anastomoses between the saphenous and deep veins, does not say what points should be selected for making the injection of chloral. On the other hand, Dr. Valerani says that the points where the varicosity is hardest and most prominent, are those where the injection should be made; they indicate the neighbourhood of the opening of an anastomosing branch, where there should be a valve, which is, however, more or less insufficient.

The operation is very simple. The injection is made with a Pravaz's syringe, the point of the needle being inserted in the largest knots of the varicose zigzag. The patient should be standing, that the veins may be more tense; if he be in bed, they are rendered tense by the finger. There is no hæmorrhage.

Valerani has seen the injection followed by softening of the clot, slight phlebitis, abscess, and sloughing; but, in spite of these complications, the result may be said to be always successful. The complications are always local, and are not attended by constitutional disturbance. It is sometimes necessary to repeat the injection, especially when the clot softens, and the vein opens and gives exit to some drops of black blood, threads of softened fibrin, and even drops of sanguinolent pus. After a longer or shorter time, the varix disappears, and the veins resume their normal dimensions, presenting the aspect of small cords, not tortuous or painful.

Dr. Valerani gives the history of several cases of large varix which he has treated with excellent result by this plan.

A. HENRY, M.D.

LEFFERTS ON FIBROID GROWTHS ON THE VOCAL CORDS.—Dr. Lefferts (*New York Medical Record*, February 2, 1874), reports two cases of fibroid growth on the vocal cords removed with the aid of the laryngoscope. In both cases, the growth was very small and situated on the anterior third of the vocal cord; in one case, the growth was removed with Störk's guillotine; in the other with Türek's forceps. In both instances, the voice was fully restored. In one of the cases, the symptoms were very anomalous; dysphagia and constant pain being the most marked symptoms, although the growth was an exceedingly small one lying entirely within the cavity of the larynx. The following is the report of this case.

A man, aged twenty-six, whilst drinking a glass of beer in January 1871, suddenly felt an obstruction in his throat. Believing that he had swallowed some foreign body, he introduced his finger into his throat as far as possible in order to remove it; this act was followed by vomiting, during which the sensation passed away. At this time he had neither difficulty of breathing, nor cough, nor had he previously noticed any alteration in his voice. Immediately after however, he observed that his voice was daily becoming weaker. The feeling, as if a foreign body were in the throat, returned at times, but the sensation was never as marked as on the first occasion. Respiration and deglutition remained normal for some time, and the patient had no pain. The weakness of

the voice, however, increased at times even to complete aphonia. In February 1873, whilst eating, the sensation as if a foreign body were in the throat suddenly returned. He described the feeling as similar to that experienced in 1871. He again attempted to remove the supposed foreign body with his finger, upon which he had a severe attack of coughing, and spat blood. After that the hoarseness rapidly increased, and for two months before the operation he was completely aphonic. He also began to have constant pain, which was aggravated by swallowing.

All the symptoms were dissipated by the removal of the growth.

MORELL MACKENZIE, M.D.

SEVERI ON HYDROCELE OF THE ROUND LIGAMENT OF THE UTERUS.—Dr. Severi (*Rivista Clinica di Bologna*, 1873, and *Gazzetta delle Cliniche*, no. 2, 1874) refers to the recorded cases of this affection, and relates the case of a young woman aged twenty, who had a swelling in the upper part of the right labium, for which, supposing it to be a hernia, she had for some time worn a truss. The absence of pain and of disturbance of digestion, the course of the malady, the narrowness of the inguinal canal, the equality in the visceral impulse on the two sides, all excluded the idea of ordinary hernia. The swelling had existed four years; and the absence of any suffering during the catamenial periods excluded the idea of ovarian hernia. It was quite transparent when examined by the light of a candle. The elongated form of the swelling and its direction along the inguinal canal led Dr. Severi to regard the case as one of hydrocele. Its contents were removed by puncture, but it refilled; a second puncture, followed by the injection of a mixture of tincture of iodine and water, effected a complete cure.

ROMEI ON FRACTURE OF THE ASTRAGALUS WITH DOUBLE DISLOCATION OF THE FOOT.—Dr. F. Romei relates in the *Bullettino delle Scienze Mediche*, May 1873 (quoted in *Gazzetta delle Cliniche*, no. 1, 1874) the case of a man named Raffaele Zecchi, who fell from a height of about two yards in getting out of a cart, and sustained a fracture of the neck of the astragalus with complete displacement of the head of the bone upwards and outwards, and dislocation outwards of the body of the astragalus, complicated with a contused and lacerated wound over the outer ankle, through which the end of the fibula projected. An attempt to replace the head of the astragalus was made, but in vain; and it was resolved to remove it. This was done by making an incision in a slightly oblique direction from within outwards over the head of the bone, and cutting through the astragalo-calcaneal ligament with scissors. By rotating the foot outwards, the astragalo-tibial dislocation was reduced; and the pain, which had been very severe, was removed.

The foot was put up in an immovable apparatus and ice was applied. On the forty-eighth day the patient was able to sit up for a great part of the day; a month later, he could put the foot to the ground without pain, and ultimately regained perfect power of walking.

As an appendix to this case, Dr. Romei relates the following, which occurred in the practice of Professor Rizzoli.

A man named Pietro Marani was thrown from a vehicle drawn by a runaway horse, and alighted on his right foot. When he was brought to the hospital two days afterwards, the sole of the foot was turned

inwards, there were two wounds in the integument of the external malleolus, and the end of the fibula projected, the leg and foot being much swollen. The limb was placed in as good a position as possible, an antiphlogistic regimen was ordered, and it was decided to delay any attempt at reduction till the foot was in a more favourable condition. The patient died of septicaemia on the twenty-second day.

The necropsy discovered an oblique fracture with displacement of the astragalus, with dislocation of the astralago-calcaneo-scaphoid articulation, and wedging of the anterior fragment of the astragalus (consisting of nearly the entire head of the bone) between the scaphoid bone and the posterior fragment.

Dr. Romei remarks that in both these cases the astragalus was broken at its neck, and in both there was dislocation of the foot, in the first above and in the second below the astragalus; and in both the obstacle to reduction was the displaced anterior fragment of the astragalus. A. HENRY, M.D.

MATERIA MEDICA AND THERAPEUTICS.

CORYLLOS ON TWO CASES OF TRAUMATIC TETANUS SUCCESSFULLY TREATED BY CHLORAL.—Dr. Coryllos reports (*Allgemeine Wiener Medizin. Zeitung*, Jan. 27) two cases of traumatic tetanus successfully treated by chloral after the removal of a foreign body from the wound.

The first case was that of a woman forty years of age, who in the month of November, 1872, wounded her right middle finger with a sharp-pointed stick. A month afterwards, when the wound had nearly healed, in the evening, after a day's washing, she had severe pain in the whole right arm, with swelling of the forearm. The next day she had a difficulty in opening the mouth and in moving her limbs; this difficulty increased until voluntary movement became impossible, and opisthotonos came on. Gradually the trismus increased, so that nourishment in the form of milk could be given only through a gap left by the previous loss of three incisor teeth. Violent tetanic paroxysms recurred more than ten

times in the twenty-four hours. After opium had been given without success, chloral was prescribed to the extent of first a drachm, then from $1\frac{1}{2}$ to 2 drachms daily. From that time the symptoms began to subside, and after a fortnight the patient complained only of weakness, but the mouth could not be fully opened until February 14.

Sixteen days after the onset of the symptoms, the patient removed from the as yet unhealed wound a piece of stick of the size of a pea, which up to that time had not been discovered. In the course of twenty days, $3\frac{1}{2}$ ounces of chloral were taken.

[The report of the case is somewhat wanting in precision, but apparently the foreign body was removed before the use of the chloral was commenced.—*Rep.*]

The second case is that of a labourer, forty years of age, who, on July 8, 1873, was wounded in the left temple by a pointed stick.

The wound, which was an inch long, was dressed with simple ointment and caused no inconvenience until July 13, when pain in the wound and swelling of the temple brought him to Dr. Coryllos for advice. There was then some difficulty in opening the mouth and some stiffness of the neck. The half-healed wound was probed, but no foreign body was detected. There was fever, and the tongue was coated. The left orbicularis palpebrarum was so contracted, that the eye could scarcely be seen. Contraction of the left levator and depressor anguli oris rendered it difficult to pass the finger between the teeth and the cheek. The left sterno-mastoid, also the omo-hyoid and sterno-hyoid muscles, were contracted so as to bend the head forwards and to the right. From time to time there occurred transient general tetanic convulsions, which increased in severity until the patient could get no rest. After a purgative, a drachm of chloral was dissolved in two ounces of water, and a table-spoonful given every hour. The patient after this dose slept all night, but the spasms returned on the following day. He went on much the same until July 16, when he was ordered to take $1\frac{1}{2}$ drachm of chloral in the twenty-four hours. The following day the pulse had fallen from 100 to 88, the mouth and the left eye were less firmly closed, and the tetanic paroxysms were less frequent. The wound had completely healed but the surrounding was swollen and tender on pressure. On July 20, all swelling having disappeared, a hard body was felt beneath the skin at one end of the scar. An incision was then made, and a sharp piece of wood three lines in length was removed. The following day another smaller piece of wood was detected by the probe and removed. During the night following the patient became excited after intercourse with his wife, he could not sleep, and endeavoured to leave the house (five years before he had suffered from mania). The tetanic symptoms returned with more violence and he again became feverish. Then $1\frac{1}{2}$ drachm of chloral was given and a grain of acetate of morphia in eight doses. After this he slept for two hours. Two days later he was still restless, and the attacks were more severe and prolonged. Two drachms of chloral were prescribed; the attacks became less frequent and violent, the mouth could be more freely opened, and some hours of quiet sleep were obtained. On August 10 there was a temporary relapse, after a short journey in a carriage; but by August 18, five weeks from the onset, he was convalescent, after taking altogether six ounces of chloral.

[One of the most interesting features of these two cases is the fact of a foreign body being discovered and removed some days after the infliction of the wound, and in one case after the wound had healed. In this respect, and in some other particulars, there is a close resemblance between these cases and two cases of traumatic tetanus recorded by the reporter in the sixth volume of the *Transactions of the Clinical Society*.—*Rep.*]

GEORGE JOHNSON, M.D.

RICE ON EMULSION OF COD-LIVER OIL.—Willard M. Rice, junior, pharmacist, offers (*American Journal of Pharmacy*, December, 1873) the following formula for the emulsion, which he thinks is superior to any other :—

| | |
|--------------------------|------------|
| B. Oleum morrhue | fl. 3viij. |
| Tragacanthæ | 3j. |
| Sacchari albi | 5iv. |
| Ol. gaultheriæ | gtt. lx. |
| Ol. sassafras | gtt. l. |
| Ol. amygd. amar. | gtt. x. |
| Aque | fl. 3viij. |

The tragacanth and sugar are to be dissolved in the water and the mucilage strained. In this are to be incorporated first the essential oils and then the cod-liver oil. This makes an elegant-looking emulsion, not too thick, containing fifty per cent of the oil, and of a rather pleasant taste and smell.

PUBLIC HEALTH.

ASSOCIATION OF MEDICAL OFFICERS OF HEALTH.

Dr. Tripe read a paper at a recent meeting on 'Density of Population and other Causes of an increased Death-rate in the Metropolis.' He said that he wished to get the opinion of the members on the best method of calculating the death-rate of a district, for different medical officers of health took varying methods of doing so. He advised that the deaths in extraneous workhouses, if any, should be cast out, as well as deaths in hospitals, and also the population of the said institutions. The death-rate should then be calculated in the population corrected to July 1 in the year, and the percentage of deaths ascertained; the percentage of deaths in hospitals for all London should be ascertained by comparison with the population of all London, and added on to the death-rate of the district. In this paper, however,

he had eliminated the deaths and population of hospitals altogether, as being less likely to lead to error. He showed that the true death-rate of the Metropolitan Districts varied between 15·2 in Hampstead per 1,000 population, and 28·6 in St. George's in the East; that in the fourteen districts having the smallest death-rates, the range extended from 15·2 to 23·2 per 1,000 inhabitants, whilst in the fourteen other districts it varied between 23·4 and 28·6 per 1,000; and that these variations corresponded to a certain extent with the density of population. The tables showed the number of persons to an acre in each of the Superintendent Registrars' Districts, which varied between 5 to an acre in Lewisham and 237 in Westminster. He showed that out of the fourteen most crowded districts no fewer than eleven had a death-rate above the mean, whilst, in the fourteen least crowded, there were eleven having a death-rate below the mean of 23·2 per 1,000 persons. The mean of the least densely populated districts was only 20·9 per 1,000, with an average of forty persons to an acre, whilst that of the most crowded districts was 24·8 per 1,000 persons, or above 20 per cent. greater.

Dr. Tripe did not attribute this great difference to variations in the density of population, as, with the exception of Westminster and one or two others, the most densely crowded districts were also the poorest. To calculate the effects of the possession of comforts on health, he had taken the proportion of servants to population, not as being the best, but as being the one least likely to lead to error. In dividing the twenty-eight districts into two sets, it was found that the percentage of servants varied in the districts having most servants between 10·7 and 4·7 per cent. of the population; and in those having the fewest servants, between 4·5 and 1·9 per 100 residents. Considering that servants are usually in the prime of life, and rarely die in the houses of their masters, it is evident that the districts having the largest percentage of servants should have the smallest rate of deaths. But the differences were greater than could arise from this only, as the death-rate of the fourteen districts having the larger proportions of servants was only 20·8 against 24·9 in the fourteen other districts having the fewest servants. Another table was drawn, in which there were three columns, the first consists of nine districts with most servants and smallest number of persons to an acre, the rate of which was 19·5 per 1,000 inhabitants; the second, of districts most crowded, with the smallest percentage of servants, in which the rate was as much as 25·7; and the last consisting of districts least crowded, or having most servants, in which the rate was 23·4 per 1,000 population. Dr. Tripe then mentioned various other causes of increased death-rate in a district, viz. the greater or less number of persons receiving parochial relief; the configuration of the district; the presence or absence of fever-dens; more or less perfect drainage; good or indifferent sanitary supervision.

MEDICAL OFFICER OF HEALTH FOR PLYMOUTH.

The Council of the Borough Corporation of Plymouth have appointed Dr. Littleton their Medical Officer of Health for one year, at a salary of 50*l*. It is sad to find that the corporation of such an important garrison and seaport town should have so little appreciation of the duties and responsibilities of a public health officer, as to offer such a small stipend. A population of 70,000 persons, by no

means in the best possible sanitary conditions, will demand all the energy of its medical officer in organising a staff, and in carrying out sanitary measures. Dr. Littleton is well calculated to perform the work entrusted to him; and will, it is hoped, give such confidence to his fellow townsmen that they cannot allow such a niggardly salary to continue very long.

OBSTETRICS AND GYNÆCOLOGY.

PORRO ON A CASE OF MALFORMED TWINS.—Dr. Edward Porro, of Milan, relates in the *Gazzetta Medica Italiana-Lombardia* for December 13, 20, and 27, 1873, and January 3, 1874, an extraordinary case of twin-birth in which both the children were misshapen.

Tr. M., a tall, well-made, healthy woman, aged twenty-two, wife of a healthy husband, with no family history of disease or of deformity, became pregnant in February, 1873. She did not perceive foetal movements till towards the end of pregnancy; nor did the abdomen enlarge until the end of October, from which time, up to her delivery on November 18, it increased rapidly, causing difficulty of defecation and respiration, and pain in the right hypochondrium. In October, she lost appetite, which she attributed to fright at seeing a man killed by a fall from a scaffold.

On November 8, the midwife in attendance on her found the os uteri dilated sufficiently to admit the finger, and perceived indistinct *ballotement* through an abundance of liquor amnii. The presentation could not be made out. Constipation and difficulty of micturition, which had troubled her, were increased.

On November 15, labour-pains set in at noon, but they produced little effect, and sometimes ceased for an hour or more. In the evening, the os uteri was dilated to about 1·2 inch. The dilatation continued, but the liquor amnii did not escape until 1 p.m. on the 17th; the pains then ceased for four hours, at the end of which time distinct expulsive efforts set in. At half-past 1 a.m. on the 18th, Dr. Porro was called to her. On examination, he found the uterus reaching eight finger-breadths above the umbilicus. The parts of a foetus could be felt through the abdominal wall. The foetal heart-sounds were heard in the umbilical region, and an uterine murmur to the left. The pelvis was normal in shape and size. The internal genitals were rather oedematous, hot, and very tender.

On examination *per vaginam*, he felt a head, buttocks, and a right and a left foot. The head presented with the forehead towards the right obturator foramen, and the occiput towards the left sacro-sciatic ligament. Behind the left horizontal ramus of the os pubis were two feet—a right and a left; the left lay in front, near the symphysis, with the dorsal surface towards the pubes and the plantar towards the sacrum. The toes were closely applied to the right parietal bone; the tarsus and metatarsus lay against the plantar surface of the right foot, which had the toes turned towards the right and the heel towards the left. Above and to the inner side of the feet, the nates were felt, closely applied to the left side of the pelvis, near the spine and the great sciatic notch. The right hip lay above and to the inner side of the right parietal protuberance. No progress could be felt during the uterine contractions.

By means of the forceps, Dr. Porro removed, with some little trouble, a living male child, malformed, which survived ten minutes. About a quarter of an hour after the birth of this child, there was a discharge of a very large quantity of liquor amnii, and the head of a second child was found presenting with the vertex in the right occipito-cotyloid position. Ten minutes afterwards, a second malformed male foetus was expelled, which breathed imperfectly, and lived eight minutes. The placenta was expelled five minutes later; there was some hæmorrhage, but this was easily restrained by cold applications to the abdomen, compression of the uterus, and the administration of ergot. The umbilical cord of the first foetus was five-and-a-half inches long, and that of the second fourteen.

The first-born foetus had the head, limbs, and trunk arranged in such a way that the body was almost spherical. The feet lay against the right parietal protuberance; the left, which was the upper one, had the dorsum turned forwards; the right, somewhat lower down, further back, and a little more to the left, had the dorsum directed backwards in contact with the right parietal bone. The right hip was affixed closely to the occipital protuberance; the left was situated in front, to the left. The sacrum looked laterally to the left, and obliquely downwards. The anal aperture was directed forwards, at the level of the right parietal protuberance. The legs were crossed together in the form of an X; the right leg lay on the right tempero-parietal region, and the left on it. The right thigh lay obliquely against the occipital and right temporal bones; the left touched the abdomen and the lower part of the right costal region, and was turned upwards and forwards. The nape of the neck was in contact with the upper dorsal region, the cervical vertebræ pressed on the pharynx, and the right shoulder rested on the mastoid region. The neck was large and short, like that of a batrachian. There was dorsal cyphosis, and left lumbar scoliosis, with slight twisting, so that the right trochanteric region touched the right temporo-parietal in an oblique direction. The thorax was keeled on the right side, the ribs there being bent at an angle. The arms were fastened down to the sides of the chest by folds of skin, attached at the middle of the humerus, giving the arms, when the skin was stretched, somewhat of the appearance of bat's wings. There was also a thick fold of skin at the fold of each elbow, preventing extension; but the joint could be moved laterally. The hands were flexed at a very acute angle, on the inner part of the forearm, and the wrists were in contact with the lower jaw. Extension of the thighs on the pelvis, and of the legs on the thighs, was limited by cutaneous folds. Both hands and feet were in a state of varus. The penis was rudimentary, and in a condition of hypospadias. The testes had not descended.

The second foetus had the head bent down on the right shoulder. The neck was very short and thick—more batrachian than in the other foetus. The right shoulder was scarcely a finger-breadth from the mastoid process. There was left dorsal scoliosis. The right humerus was articulated normally with the scapula; the left was fastened in its upper third to the thorax by a fold of skin. The bands of the elbows were normal. The forearms were somewhat malformed; the right radiocarpal joint was bent at an acute angle. The palm of the right hand lay in contact with the anterior surface

of the forearm; the ring and little fingers were bent, and could not be extended. The left upper limb presented the same relations of the forearm to the hand; the fingers were at a right angle with the carpus, and the phalanges were bent on the palm; the thumb was normal. The thighs were bent at an obtuse angle on the pelvis, and could not be extended in consequence of the deficiency of the integuments. The relations of the head of the femur to the ace-

tabulum were normal on both sides. The right leg was bent at a right angle on the thigh; and the left at an obtuse angle. The right foot was joined to the leg at a very acute angle, with the sole turned forward. The left foot had the dorsum turned forwards, with the outer edge downwards, and the toes backwards and inwards. The scrotum was wanting, and the penis rudimentary; the testes could not be felt in the inguinal canal. A. HENRY, M.D.

NEW INVENTIONS.

AN IMPROVED SYPHON STOMACH-PUMP.

Mr. L. H. Tosswill of Exeter has devised an apparatus which he thus describes.

For some time past, I have felt convinced that the stomach-pump now in use is far from a perfect apparatus. It is costly, not particularly portable, and, above all, a dangerous instrument, cases being known where the stomach-tube has been pushed through the coats of the stomach or œsophagus. I wish, therefore, to bring before the notice of the profession a stomach-pump on a novel principle, which has been made for me by Messrs. Arnold and Sons, the well known instrument-makers in West Smithfield. The advantages I claim for my instrument are freedom from danger, cheapness, and increased portability. It can be easily carried in the coat pocket, its cost does not exceed 15s., and it is almost impossible to perforate the coats of the stomach or œsophagus by means of it, be the operator ever so clumsy or ignorant. The instrument consists of an India-rubber tube, about half an inch in diameter and four feet in length, provided with a ball of the same material, which is three or four inches in diameter, and situated about eighteen inches from one end of it. In fact, it is almost a *fac simile* of one of Higginson's enema syringes, but without a valve. To the shorter length of tube the stomach-tube proper is attached by a simple contrivance. This stomach-tube is nothing more or less than an enlarged Thompson's India-rubber catheter, with two large oval holes situated near the extremity. Let us suppose the instrument to be used in a case of poisoning, where it is desired to wash out the stomach as speedily as possible. The patient being seated in a chair, or reclining on a couch, the stomach-tube is oiled and then passed back in the mouth in the usual way, until it has reached the upper part of the pharynx. Its passage down the œsophagus, as in the case of Thompson's catheter in the urethra, is effected by twisting it round and round in the hand until it has reached the stomach. I need scarcely point out how much less pain this soft flexible tube

must cause than the hard somewhat inelastic tube generally used. The rest of the instrument is now adjusted to the stomach-tube, the work of a second, and then, a jug of water being obtained, the end of the tube beyond the ball is introduced into it. The operator, with one hand pinching the India-rubber tube somewhere between the ball and the patient's mouth, with the other compresses the elastic ball, and thus forces out some of the air contained in it, which bubbles up through the water in the jug. When this has been repeated two or three times, all the air is forced out, and the ball becomes filled with water. If the jug be now raised a foot or two above the patient's stomach, and the pinching of the tube be discontinued, the instrument acts as once as a syphon, and the water flows from the jug in a continuous stream into the patient's stomach. When enough has been introduced, the tube is pinched somewhere between the ball and the patient's mouth, and the flow of water into the patient's stomach is at once stopped, the water being retained in the ball by the atmospheric pressure. If the end of the tube be now taken out of the jug and put into a basin, below the level of the patient's stomach, upon the pinching of the tube being discontinued, the contents of the stomach will at once flow out into the basin in a continuous stream; the instrument acting, of course, again as a syphon, only in the reverse way to that previously. When it is considered that the stomach is nearly empty, the tube is pinched between the ball and the basin, the end of the tube put back into the jug, and the whole thing repeated over again.

Two deaths from cholera occurred in Utrecht, and one in Gouda, in the week ending February 14.

The *Correio Medico de Lisboa* says that for some time the San José hospital has been overcrowded, and that erysipelas, diarrhoea, and other manifestations of septiciæmia, have been and still are prevalent.

ELECTRO-THERAPEUTICS.

BYRNE ON THE ELECTRIC CAUTERY IN UTERINE SURGERY.—Dr. J. Byrne, of New York, in his recent work on this subject, submits the following aphorisms regarding the operative procedures in use.

1. In all cases of induration, destructive ulceration, and outgrowths of the cervix uteri of a malignant nature, or believed to be so, and therefore warranting excision by galvano-cautery or other means, such operations should never be limited to the apparent line of demarcation between sound and healthy tissue, but must include the whole vaginal cervix at least, and even more if need be. 2. When the shape of a part to be excised is such that a loop can not be made to embrace it, a circular furrow for the reception of the wire may first be made by the cautery knife. 3. The wire loop, knife, or other instrument should never be brought to a white heat when passing through superficial tissues or cellular growths. 4. Traction on the part to be excised should be carefully avoided until the wire has passed well into the submucous structures. 5. The contraction of the loop should in all cases be very slow and gradual, *yet interrupted*, so as to insure a thorough cauterisation of each stratum as passed through. 6. Toward the close of such operations, and as the circle of wire becomes very small, let the amount of electricity be proportionately lessened. 7. Apply the knife to the spot intended to be cut *before heating*, and, if possible, be always provided with a duplicate of this little instrument. 8. Shun the use of persulphate of iron as a utero-vaginal styptic dressing when possible; and, should any such agent be needed, substitute solutions of alum or acetic acid, dilute or strong, as circumstances may warrant.

REVIEW.

Osservazioni Anatomiche per servire allo Studio della Circolazione venosa delle Estremità inferiori. [Anatomical Details to assist in the study of the Venous Circulation in the Lower Limbs.]—A memoir read to the Academy of Medicine at Turin and extracted from their Journal. By DR. CARLO GIACOMINI, &c.

The first part of this memoir treats of the superficial veins, and chiefly of the external or short saphenous.

The author first enumerates the various, more or less abnormal methods in which this vein may terminate. These he arranges in the following order.

1. There may be an anastomotic branch communicating upwards with the internal or long saphenous vein. He gives numerous ways in which this anastomosis may occur, and he says that some such communication is so frequent, that he regards the giving off of a branch from the external saphenous just previous to its termination in the popliteal, to form an anastomosis with the long saphenous, not as an anomaly (as Cruveilhier describes it) but as a normal state. This branch, however, may run in one of several different courses, forming sometimes also a communication with the articular veins.

2. The second is a branch which runs along with the small sciatic nerve on the back of the thigh, and joins the external saphenous, or connects the latter

with the before-mentioned anastomotic branch to the internal saphenous. This branch may sometimes be much enlarged, and may form an anastomosis with the short saphenous and the gluteal or sciatic veins. These superior anastomoses in some cases are so large that the portion of the short saphenous which opens into the popliteal is very small or even wanting altogether, so that the external opens into the internal saphenous only.

3. There are other and more numerous anastomoses in the leg between the two saphenous veins; and other cases in which the short saphenous goes entirely into the internal saphenous vein. In these instances the vein is not truly subcutaneous, but is contained between two layers of the deep fascia.

4. Other anastomosing branches proceed to the deep veins, the most common of which communicates between one of the perforating veins and the above mentioned anastomosing branch to the long saphenous.

5. Another anastomosing branch runs from the external saphenous, through the substance of the short head of the biceps to the profunda femoris vein, and finally—

6. The whole external saphenous vein, instead of merely an anastomosing branch, may pass into one of the perforating.

When the external saphenous vein has pierced the aponeurosis of the popliteal space, it sometimes runs upwards for some distance before it unites with the popliteal vein, receiving in its course some of the branches which generally open into that vein; and about once in three times the vein, instead of passing between the two great divisions of the sciatic nerve to open into the popliteal, runs at the inner side of the internal popliteal nerve.

A table is added of the results of fifty-one dissections—the numbers are hardly worth quoting—the most striking fact is that in only three cases out of the fifty-one did the short saphenous terminate entirely in the popliteal without any other anastomosis.

The second part of the memoir contains an account of thirteen dissections in which (the arteries being normal) abnormalities were found in the popliteal and femoral veins. The popliteal vein was frequently found to be double. It terminated sometimes in the profunda femoris vein, leaving the superficial femoral artery without any companion vein, or bifurcated into the superficial and deep femoral veins. At other times a *vas aberrans* united the deep to the superficial femoral vein, or other anomalous communications were found between various deep veins of the limb. The author also lays stress on the frequent occurrence of 'venous islets' in the deep veins of the lower limb—formed by the division and subsequent reunion of a trunk vein.

The third part consists of some observations on the lower animals.

In summing up his observations in the fourth and concluding portion of his treatise, the author first notices the fact that the great arteries of the limb may in some cases be found surrounded by a tight network of interlacing veins, while in others they may have no accompanying vein at all.

But the part of his work on which he lays most stress is the study which he has made of the anastomoses between the superficial and deep veins. These branches he classifies into inter- and intra-muscular, and in these he says the valves are always very numerous, and so directed as to favour the passage of the blood from the superficial into the deep veins,

but to oppose all reflux from the deep into the superficial. He refers to other authors viz. Houzé d'Aulnoit, Verneuil, and Le Dentu, who have made the same observation.

From this consideration he is led to oppose the views of those who (with Mr. Gay*) look upon the superficial veins as a kind of supplement or diverticulum to the deep venous system. He says, on the contrary, that in the normal condition of the veins—*i.e.* when the valves of the anastomosing system (inter- and intra-muscular) between the deep and superficial veins are efficient, it is impossible for the blood to flow back from the deep veins into the saphenous or their branches, and equally impossible to inject the saphenous veins from one of the deep, *e.g.*, the posterior tibial, though the deep system can always be injected from the radicles of the saphenous. When the superficial veins become varicose, the cause, according to him, will always be found in varicosity of the anastomosing system of veins, and consequent insufficiency of their valves—whereby the column of blood is thrown back from the deep veins on to the saphenous and their branches, which, not being supported by muscles or fasciæ, easily yield.

In support of this he refers to numerous dissections, in one of which he found the secondary subcutaneous veins varicose, but the saphenous veins were not so, and in this instance he discovered that the anastomosing system was in direct connexion with the secondary veins, and not with the saphenous trunks.

He believes, therefore, that the subcutaneous veins are not primarily affected with varix, but that this condition in them is secondary to a varicose state of the deep veins, though how that condition is produced in the deeper veins he is unable to say.

T. HOLMES.

MISCELLANY.

COUNT BASILIO STAMPA, who died lately in Milan, has left, after providing for his family and servants, 400*l.* to the hospital at Desio, and 1,200*l.* each to the hospitals at Veprio and Saronno.

TRICHINOSIS.—At the town of Forst, in Germany, twenty-two persons have been attacked with trichinosis through eating the flesh of a pig killed by an hotel keeper. The cook and the hotel keeper have both died; the body of the former was found full of living trichinæ. Several other persons were, on February 24, dangerously ill, and new cases were coming under notice.

THE BRITISH PHARMACOPEIA.—We have authority to state that a new edition of this valuable official work will be issued next week. An important 'addendum' will contain formulæ for new remedies which have been introduced into practice since the last edition was published. The main labour of its production has fallen upon Dr. Quain, F.R.S., and Professor Redwood.

MEDICAL APPOINTMENTS.—Among the more important medical appointments of the week are those of Mr. Field to St. Mark's Hospital, and Dr. Galabin to Guy's and the Children's Hospitals. Dr. Galabin was a Fellow of Trinity College, and was, we believe, second classic and a Smith's prizeman. We hear also that Mr. Harding, the senior wrangler of last year, is studying physiology in Dr. Foster's laboratory. It is satisfactory to find that medical studies are once more attracting the best learned minds of the University. Law and the Church have too long enjoyed a monopoly of wranglers and first-class men in classics.

* *Lancet*, vol. ii. 1871, 629.

THE GOVERNMENT AND THE MEDICAL COUNCIL.—The new Government, following out arrangements of their predecessors on the point of completion, have offered to the General Medical Council the premises in Oxford Street formerly occupied by the College of Chemistry. They are offered at a very moderate rent. Mr. Lowe, however, had admitted the right of the Council to premises free of rent.

PROFESSIONAL WOMEN.—Mrs. Garrett Anderson, M.D., has been proposed as a member of the Obstetrical Society of London by Dr. Tilt, president of the Society, Dr. Priestley, Dr. Barnes, Dr. Playfair, Dr. Braxton Hicks, F.R.S., Dr. Oldham, Dr. G. Hewitt, and other members of the obstetric branch of the profession. This has raised the question of the right of women, although duly qualified, to be elected members of that Society, and the question will be discussed this evening at a general meeting.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.—At the anniversary meeting of this society, held on Monday, March 2, the following officers, and other members of Council were elected for the year 1874-1875. President: Charles J. B. Williams, M.D., F.R.S. Vice-Presidents: E. H. Sieveking, M.D.; Sir W. W. Gull, Bart., M.D., D.C.L., F.R.S.; W. White Cooper; Luther Holden. Treasurers: W. Wegg, M.D.; J. Birkett. Secretaries: E. Symes Thompson, M.D.; J. Cooper Forster. Librarians: F. Sibson, M.D., F.R.S.; T. Holmes. Other Members of Council: J. B. Carill, M.D.; W. H. Dickinson, M.D.; C. J. Hare, M.D.; W. O. Priestley, M.D.; H. Weber, M.D.; W. Adams; T. Bryant; G. W. Calender, F.R.S.; John Gay; J. F. Streatfield.

CHEAP FOOD.—We are very glad to see that the results of the large importations of Australian meat into this country during the last year appear to have been commercially successful. Owing to the increased value of sheep from the high price of wool, there was a smaller importation of preserved meat from Victoria last year than in the year before, and many large orders received by Tallerman's Australian Meat Agency could not be executed. During the year 13,061 tons of animal food have been added to our home resources from the Australian Colonies, and have been sold at a value of 733,848*l.* The Continental demand is increasing. It is a curious fact that, while the consumption of the meat by the poorer classes has decreased, the better educated classes are creating an extended and permanent demand for these meats through the higher class of dealers. The Australian Meat Agency declares a dividend of 10 per cent per annum, and the prospect of commercial stability of this important branch of trade is thus decidedly increasing.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 1*rs.* 4*d.*; free by post, 1*rs.* 6*d.*

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 1*rs.* 6*d.* Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the Editor, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MARCH 11, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

DAY ON THE CHEMICAL PROPERTIES AND PHYSIOLOGICAL ACTION OF FAT.

In an interesting paper read before the Medical Society of Victoria (*Australian Medical Journal* November, 1873), Dr. John Day submitted for consideration the results of a series of experiments on which he had recently been engaged, with a view to ascertain, if possible, the nature of the change produced in fats by exposure to the atmosphere. He said :

'It is well known that all fats and fatty oils, whether derived from the animal or the vegetable kingdom, possess the property, more or less, of absorbing oxygen from the atmosphere, and that, when long exposed to its influence, some become rancid, and others are converted into *drying oils*; but, beyond this, no attempt, that I am aware of, has hitherto been made to show the true nature of the change which the oxygen undergoes after it has been absorbed.

'Now, my investigations have led me to believe that it is invariably converted into peroxide of hydrogen—a substance possessed of very remarkable properties, particularly when looked at from a physiological point of view.

'It has been stated by Professor Roscoe, one of our most eminent modern authorities on chemistry, that peroxide of hydrogen, which he calls hydrogen di-oxide, does not occur in nature. On this point I venture to express a difference of opinion, and would even go so far as to say that spontaneously formed peroxide of hydrogen exists in a very large number of substances, many of which are articles of everyday use. For instance, it may often be found, and sometimes in considerable quantities, in kerosene, gasoline, benzine, oil of turpentine, and many kinds of perfumery. With these, however, we have, on the present occasion, no special concern.

'It is its universal presence in all fats and fatty oils, with the exception of the fats of recently killed animals, its absence from which I believe I can explain, that I have undertaken to prove this evening, and I will at once proceed with the attempt.

'On the table before us are various unselected specimens of the following substances belonging to this class of hydrocarbons, in all of which I have very clearly detected the presence of peroxide of hydrogen; viz., the fat of beef, mutton, and pork, beef-marrow, bone-grease, beef and mutton tallow, fresh butter, prepared lard, neatsfoot oil, cocoa-nut oil, palm oil, cacao-butter, almond, castor, olive, and linseed oils, and stearine.

'There are several tests for the presence of per-

oxide of hydrogen; but the two best for our purpose are the iodide of potassium, and the guaiacum and blood tests.

'The iodide of potassium test is open to the objection that it gives the same reaction with ozone as it does with peroxide of hydrogen, which, according to Schönbein, is antozone in loose combination with water. This very objection, however, to its general value as a test for peroxide of hydrogen rather assists us on the present occasion, for it shows us that the oxygen which has been absorbed by these substances, must have undergone a change and acquired increased oxidising powers, otherwise it would not be capable, as it invariably is, of liberating iodine from iodide of potassium—a property which common oxygen does not possess.

'This change in the oxidising powers of the absorbed oxygen leads us to infer that it has been converted either into ozone or peroxide of hydrogen.

'The guaiacum and blood-test, which is perfectly reliable, will carry us a step further, and teach us that it is peroxide of hydrogen, and not ozone, which has been formed; for one of the characteristic properties of ozone is its power of oxidising and turning blue the resin of guaiacum, a property which, as I will presently show you, peroxide of hydrogen only possesses under very peculiar circumstances, viz. when it is brought into contact with either blood or pus. It then acquires greatly increased oxidising powers, and gives the reactions of ozone.

'As the reactions from both these tests become more marked after the lapse of a little time, I have already applied them to each of the specimens before you, so that you may see them to the best advantage. I will also repeat the experiments before you on some of those substances in which the presence of peroxide of hydrogen appears to me to be the most interesting, such as cod-liver oil, olive oil, fresh butter, beef and mutton fats, lard, cocoa-nut oil, and palm oil.

'To gain satisfactory results, it is best to perform the experiments on white blotting-paper, taking care that it does not, in itself, contain anything which could act on the guaiacum-resin and turn it blue.

'The tincture of guaiacum used for the purpose must be a simple solution of the resin in alcohol, not the ammoniated tincture of the *British Pharmacopæia*.

'A watery solution of dried blood gives the quickest reaction; but fresh undiluted blood will also give it very readily.

'The blood should be applied to the paper first; then the fat or fatty oil; and lastly the tincture of guaiacum.

'The greatest difficulty I have had to contend against in these investigations has been to find some satisfactory mode of accounting for the absence of peroxide of hydrogen in the fat of recently killed animals; but I think I am now able to explain it.

'You have already seen that peroxide of hydrogen is rapidly changed and converted into another and more active form of oxygen in the presence of blood. Now, when we consider that in the living body the fats are in a fluid or nearly fluid state, and freely brought under the influence of the blood-corpuscles, the colouring matter of which is supposed to be chiefly instrumental in effecting this change, it is not difficult to arrive at a tolerably plausible hypothesis regarding the absence of peroxide of hydrogen, in the fats of recently killed animals.

'The following experiment, I think, favours the view that fats are incessantly generating peroxide of hydrogen, and that the only circumstances under

which it does not accumulate in them are those in which blood, or some other substance capable of destroying it, is present. On October 19th, I put the fat of some beef, which was killed on the 10th, into the oven at a temperature of 100° Fahr., as nearly as I could manage it, and left it there for four hours; at the expiration of that time it had become pretty strongly charged with peroxide of hydrogen, although before it was put into the oven it did not show a trace of it.

'My mode of accounting for this change is as follows. The fat was rendered fluid by the agency of heat, and this condition brought the colouring matter of the blood and the peroxide of hydrogen of the fat into closer contact, and thus led to their mutual destruction; and this went on until the whole of the colouring matter of the blood had been destroyed. The peroxide of hydrogen then began to accumulate.

'On applying the guaiacum test for blood to the fat before it was placed in the oven, I got the characteristic blue reaction very freely; but after it was taken out and allowed to cool, the test, although one of extreme delicacy, gave no evidence whatever of the presence of blood.

'It has been suggested to me by a scientific friend that, if it be true that so many substances in common use contain peroxide of hydrogen, it might rather detract from the value of the guaiacum process for the detection of blood in medico-legal cases; a test with which my name has become associated. But this really forms no valid objection to its use, from the simple fact that blood falling on cloth or any other article containing peroxide of hydrogen would very quickly decompose it.

'Now, although I feel tolerably confident in the correctness of my views regarding the chemical changes which oxygen undergoes after its absorption by fats, I am free to confess that the physiological views I have undertaken to bring before you are of a purely speculative character. Nevertheless, if we see reason to believe that fats in the living body produce the same changes in the inspired oxygen that fats out of the body produce in atmospheric oxygen, it will offer us sufficient encouragement to pursue these inquiries further; and I do not think I claim too much in saying that they may lead to valuable results.

'My present belief is, that fats, either in or out of the body, are incessantly absorbing oxygen and converting it into peroxide of hydrogen; that in the body they produce the first change in the inspired oxygen, and convert it into peroxide of hydrogen, ready for conversion, through the agency of the blood-corpuscles, into some still more active form of oxygen—probably ozone.

'In conclusion, I will briefly mention those points in the chemical properties of peroxide of hydrogen, which are possessed of the greatest physiological interest.

'1. It is a powerful oxidising substance, and is chiefly characterised by the ease with which it parts with half its oxygen. Its oxidising powers are much greater than those of common oxygen, but less than those of ozone, into which it is supposed to be converted in the presence of blood.

'2 It is chemically indifferent to albumen, and may be kept for a long time in contact with it, without undergoing change; in this respect it differs widely from ozone, which acts energetically on albuminoid substances, particularly when they are beginning to decay.

'3. It is destroyed by heat.

'Now, assuming that peroxide of hydrogen is a normal constituent of fat, this last-named property may help to explain why persons suffering from rheumatic fever and other diseases in which the temperature of the body rises to 107° Fahr. invariably die; for we are told by writers on chemistry, that peroxide of hydrogen begins to decompose at 100° Fahr., and that it decomposes with great rapidity at higher temperatures.'

CZERNY ON LOCAL OSTEOMALACIA OF THE LEG.*

Dr. Czerny of Freiburg relates a case of this uncommon affection, and makes some interesting remarks which are worthy of a somewhat full report. The paper is accompanied by a woodcut, illustrating the deformity, which at first sight looks like a badly healed fracture.

S. Rafael, aged twenty-two, served as a soldier during the recent war, and made the forced march which preceded the siege of Belfort. At that time he felt and complained of shooting pains at the inner side of the left ankle, which rendered necessary a short stay in the hospital. He soon became better and continued his service. After the war, he worked as a mechanic. He came to the Clinic on March 12, 1872. There was some swelling at the inner side of the ankle, which was not sensitive to pressure. He complained that, after long standing, there was great pains in both ankles. The affected foot was somewhat flatter than the other, which made Dr. Czerny think it might probably be a case of commencing talipes valgus. Rest and moist applications soon relieved the symptoms, and the patient was discharged on March 27 with a Stromeier's shoe.

Some weeks later he returned to the hospital, and complained that the improvement was only temporary, that the pains were now in the lower part of the shin. There were slight œdema and pain on pressure, and he could not use his foot for any time, so that on May 6 he was admitted into the Clinic. At this time there was a slight bending of the tibia, which was thickened at the anterior edge. Dr. Czerny then thought it was a case of chronic osteitis, and applied a gypsum bandage, leaving an opening over the seat of pain, where iodine was applied. The pains disappeared after some weeks; and, as the patient wished to be discharged, he was dismissed with an isinglass bandage.

During his stay in hospital the deformity did not increase, but afterwards the patient did not have his bandage renewed, and through constant use of the leg it became considerably bent. On February 8, 1873, he was re-admitted. The left tibia at its lower third was bent at an obtuse angle, so that the tendo Achillis was strongly arched inwards. At the seat of the greatest bending, both bones appeared thickened. On attempting gently to bend the bones with the hands no pain was produced, but there was no yielding. The muscles of the calf were rather weaker than those of the opposite side. The foot appeared as if slightly affected with talipes equinovaglus.

The man could walk with the help of a stick, but was soon tired, and complained of pain in the ankle after long use, which Dr. Czerny thought to be probably due to stretching of the ligaments. In other

* *Wiener Med. Wochenschrift*, no. 39, 1873.

respects the man appeared in good health, and there was no affection of the other bones.

On July 12, 1873, the condition had not changed. In case the functional disturbance should increase, Dr. Czerny suggested forcible straightening of the bones with, or without, osteotomy; but the patient was loth to acquiesce.

Cases of this kind are so rare, that it is worth while to quote those which one can find scattered in medical literature. Scoutetten (*Gazette Médicale de Paris*, 1841, p. 428) reports the case of a tailor, aged twenty-five, who was otherwise in good health, but who suffered from severe pains in the lower portion of one leg, which was followed by gradual bending of the part, so that finally it gave way or cracked at a right angle. The foot was in the position of extreme valgus. The bones firmly united, so that he became a postman, and walked eight or ten miles daily. The ankle-joint was healthy, and the deformity affected the bones just above the joint. Scoutetten ascribes this deformity to a partial osteomalacia, which developed itself without any known cause, and considered the case unique.

Solly (*Medico-Chirurgical Transactions*, vol. xxvii., 1844) describes two cases which, he concludes, were due to local osteomalacia, and which appeared to belong to this category. In a man aged thirty, one leg gradually became bent, the integuments thickened and ulcerated, and the general health was disturbed so much that amputation was performed. The tibia and fibula showed very loose lamellæ, which were very thin and fragile, filled with a soft red mass.

Another man, aged thirty, suffered manifestly from softening of one thigh, which was fractured from a very slight cause. The bone was much thickened and bent. An apparatus was procured for him, by means of which the weight on this side was transferred from the thigh to the pelvis, and thus he was enabled to walk and to work.

Mosetig (*Wiener Medizinische Presse*, 1868, no. 4, p. 89), describes, under the name of osteo-haliteresis, a case of local softening of the bones of the leg. The patient, aged twenty-one, had the year before, during dancing, suddenly felt a very violent pain, which, however, did not prevent him from continuing to dance, after a short rest. Since that time he had occasionally felt slight pains, and observed, for the first time, about Christmas, 1866, that his leg commenced to bend a little above the malleoli. The curvature increased constantly, and at last rendered walking impossible, so that the patient entered the Clinic in July. The direction of the curve was outward, and corresponded to an angle of 130 degrees; the foot was in the valgus position. The bones were not enlarged at the seat of curvature. They were smooth, and there was no solution of continuity. By daily cautious bending and the application of wooden splints, the limb was quite straight in four weeks. After this the patient was further treated with splints, &c., until the bone became perfectly firm. R. Volkmann adds the following remark. The assumption of the author that in such cases of gradual curvature of the bones we constantly find a haliteresis, *i.e.* a partial decalcification while the cartilage remains normal, rests on an error. Much more frequently there shows itself, as so-called rarefying osteitis, an increase of the medullary space, and in necrosis (in which Mosetig saw curvatures twice), there was usually an internal fracture.

Weinlechner (*Wochenschrift der Gesellschaft der*

Aerzte in Wien, vol. 25, p. 21,) saw two cases. A strong butcher, aged between twenty and thirty, had a curvature of the right leg and pain, which prevented him from walking. No injury had preceded it. The bone exfoliated (*federte*). A labourer, aged nineteen, who had been ill for nine months, had both legs bent, the one with the apex of the angle outwards, the other inwards. Here also pain existed. The bone exfoliated. Splints and good nourishment formed the therapeutics. On dismissal, both legs were still pliable.

The cases of Scoutetten, Mosetig, and Weinlechner are extremely like Dr. Czerny's. In all six patients, who were strong men of the labouring class, and were of that age in which the growth of the length of the skeleton ceases, a curvature of the legs above the ankle was gradually developed, and was accompanied by pain, which did not, however, prevent the use of the limb. The limbs were at first pliable, but in some cases became unpliant and hard.

We must here suppose a sclerosis of the bones, if we take into consideration the perfect recovery of the functions in such unfavourable mechanical conditions as in the case of Scoutetten. We have no certain data on the cause of this peculiar affection, if we are not to consider as such the much maligned cold-catching which occurs commonly in dancing or in long marches in deep snow (Dr. Czerny's case). Mosetig assumes, in his case, an injury. In none of the patients is a dyscrasia or a hereditary predisposition mentioned. Solly's first case seems also to belong to this class, but is not very clear (as given in Hodgson's short report) how long the disease had lasted, whether the disease of the bone had gone on to the formation of pus and ulceration of skin, or whether an ulcer of the skin had been developed at the place of curvature and independent of it, which became so burdensome to the patient that he submitted to amputation. It is probable that the patient could not use his leg for walking, otherwise he would not have so readily submitted to amputation. Unfortunately, we cannot on this account learn anything from this meagre anatomical result, which, so far as Dr. Czerny knows, is the only one which has been examined; and he cannot find out whether Volkmann was induced by other anatomical researches to communicate his remarks concerning this disease.

Solly's second case must rather be ascribed to a senile osteoporosis, and cannot well be explained without an anatomical examination. Cases of local osteomalacia of individual bones, as of the sternum, cranial bones, &c., which always ending fatally, cannot have anything in common with this disease. The fact of the softening frequently end in sclerosis might make one incline to the diagnosis of delayed rachitis, but the affection in these cases was a purely local one, and there was more inflammation than in rickets. The name osteo-haliteresis only explains a part of the diseased process; as all the characters of osteitis ending with sclerosis were present, the term osteitis deformans seems more applicable.

Dr. Czerny thinks that, when attention has been sufficiently drawn to this disease, cases will be more often recognised. Syphilis may be a cause of bending of bones; and shortly after this case one due to syphilis came under Dr. Czerny's care, and was cured by iodide of potassium, splints, and rest. Syphilis may be suspected in cases of osteitis deformans; and iodide of potassium should be tried.

[A woman, aged fifty, but looking older, is now among our out-patients, and came complaining that

her legs were bending. One—the right—had commenced to do so three years ago, and the left only during the last fourteen months. Both tibiae were considerably curved forwards, and at first sight we were inclined to regard the case as an old standing one, *i.e.*, that she had been the subject of rickets when a child, and that her history was not reliable; but at a subsequent visit she was questioned very closely, and her daughter said that her mother's legs had only commenced to curve during the last three years. This induced us to regard the case as one of so-called senile rickets, and as several features resembled those of the cases of Dr. Czerny, we have thought it well to append a brief notice of it.—*Rep.*]

H. A. REEVES.

PARKES ON THE EFFECTS OF ALCOHOL.*

Dr. Parkes has made a large number of experiments on a strong healthy soldier, T. R., aged twenty-five, height 5 ft. 8½ in., weight (naked) 67·46 kilogrammes, or 148 lbs.

The course of the experiments was as follows. His breakfast was taken at 6·30, was finished every day by 7 A.M.; he took for breakfast eight ounces of bread, ½ ounce of butter, and 17 fluid ounces of tea with sugar, and with three ounces of milk. Immediately after breakfast he went to bed again, and did not get out of the recumbent position for any purpose until 2 o'clock. He then dined on 12 ounces of beef-steak, 4 ounces of bread, and 8 ounces of water.

After dinner he took exercise and smoked, had tea (same food as at breakfast) at 6, and a glass of water at 9 P.M., when he went to bed. He took daily precisely the same diet and quantity of water.

Thermometers (tested for accuracy and exactly corresponding) were placed in the axilla and rectum at 6 o'clock, and, except at breakfast, they were removed only for the purpose of being read at first every thirty, and then every fifteen minutes, and were at once replaced, until 2 o'clock; after which time the temperatures were only taken every two hours.

After several days' preliminary examination (during which time he took no alcohol) the experiments were commenced and carried on for six days without alcohol; then during five days undiluted brandy containing 50 per cent. of absolute alcohol was given once daily, *viz.* at 11 A.M., four hours after breakfast.

On the first day one fluid ounce of brandy (= half an ounce of alcohol) was given; on the second day two ounces, on the third day four ounces, on the fourth day six ounces (= three ounces of alcohol), and on the fifth day also six ounces.

The following were the conclusions arrived at.

1. The change in the temperature of the axilla and rectum produced by brandy was very slight. It was never increased, but was probably slightly lowered; but the result is not quite certain; and if any lowering occurred, it did not exceed 0·35° Fahr., and may not have been more than 0·07° Fahr.

2. The pulse, which was lessened in number by long rest in a recumbent position, was increased in frequency by a single dose of brandy for three hours, but subsequently fell in number, so that the daily work done by the heart was the same on the water

and the brandy days. What occurred was accelerated work for a certain time, and compensation for this by lessened work afterwards. That brandy increases the force as well as the number of the pulse, was shown by sphygmographic tracings in the papers already communicated to the Royal Society; and in order not to disturb the state of rest, no sphygmographic observations were taken in this case.

3. The respirations appeared to be slightly lessened by brandy; but the evidence is not very strong.

The author made another series of experiments to determine the effect of alcohol after sixteen hours fasting.

The following conclusions may be drawn from the observations formerly recorded (*Proceedings of the Royal Society*, nos. 120, 123, and 136), and from those now laid before the Royal Society.

1. When alcohol in dietetic doses (= 2 fluid ounces, or 57 cubic centimetres, of absolute alcohol) was given to a healthy man fasting and at rest, a decided though slight lowering of bodily temperature (as judged of by the heat of the rectum) was caused. The amount of lowering was under half a degree of Fahrenheit; and sometimes even this amount was not perceptible, being probably counteracted by the opposing influence of the heat-producing changes in the body, which cause slight variations of temperature independent of food and movement. The greatest effect was produced about from one to two hours after the alcohol was taken, and the effect was evidently passing off in three hours.

2. When alcohol in dietetic doses was given to a healthy man at rest, and in whom the process of digestion was completed, and whose temperature, raised by the food, was again commencing to fall, a lessening of temperature was also proved, but its amount was not so great; it could not have been more than 0·35° Fahr., and may have been only 0·07° Fahr.

3. When alcohol was given with food with either usual or increased exercise, no effect on temperature was perceptible, even though the alcohol was given in large quantities, *viz.* from four to eight fluid ounces of absolute alcohol (114 to 227 cub. centims.) in twenty-four hours. It is to be presumed that the amount of heat generated from the food and movement concealed the effect of the alcohol, which would require a more delicate method for detection.

4. In no case did alcohol raise the temperature.

5. The effect of alcohol on the pulse was uniform in the four men experimented upon. The contractions of the heart were more frequent during complete rest, from five to ten beats per minute for some time; and when exercise was taken the increase was greater. The mean pulse of the twenty-four hours was, however, not increased unless the amount of alcohol was large and repeated. In other words, the heart's beats were less frequent than natural when the effect of the alcohol had passed off. The pulse became both fuller and softer to the touch; and this relaxation of the radial artery was shown also by the sphygmograph. That the smaller vessels were relaxed was shown by the redness of the surface and by the evident ease with which the blood traversed the capillaries, as shown by the sphygmographic tracings.

6. The respirations were not increased in number by alcohol; they were indeed lessened, and were deeper in some of the experiments; but the effect was not very marked.

ANATOMY AND PHYSIOLOGY.

PHYSIOLOGICAL RESEARCHES ON DIGESTION AND ABSORPTION IN THE HUMAN LARGE INTESTINE. BY V. CZERNY AND J. LATSCHENBERGER, OF FREIBURG.*

The opinions of authors† who have investigated the functions of the intestinal canal in nutrition are much divided on the two chief questions—the digestive action of the intestinal juice on the one hand, and the absorption of the intestinal contents on the other. The older experimenters, Leuret and Lasaigne, Gmelin, Eberle, and Steinhäuser, whose results indeed, on account of the insufficiency of the methods of research, have not very much weight, came to the conclusion that the intestinal juice possesses a digestive power. Blondlot first impugned this positive result, and was soon supported by the exact researches of Frerichs. At a later period, Zander, working under the direction of Bidder and

Schmidt, again adopted the older view. Busch, also, who made experiments in a case of fistula of the small intestine in the human subject, obtained a digestive action on albuminates and starch. Kölliker and H. Müller defended the opinion that the intestinal juice was capable of digesting the albuminates, at least in carnivora. On the other hand, Braune and Funke found all digestive action wanting. According to Thiry, the intestinal secretion is destitute of digestive power, fibrin only being dissolved by it. Schiff asserts that other albuminates also are digested; while Quincke obtained perfectly negative results, and in many cases could not even observe that fibrin was digested. In like manner Eichhorst has not been able in his experiments to ascertain that the intestinal juice has any digestive power.

Quite as contradictory are the opinions on the manner in which nutritive materials are absorbed in the intestinal canal. Those who assume that absorption is a diffusion-process, and that soluble albumen is diffused with great difficulty and the peptones on the contrary very easily, are of opinion that albuminates are changed into peptone, absorbed as such, and then again converted into soluble albumen. This opinion, supported by Mulder, Meissner, Hermann, &c., is opposed by Brücke, who, among other important reasons, lays special stress on the fact that it is inconsistent with the fundamental principle of the animal organism, that bodies possessing slight cohesion, such as peptones, should be reconstructed into bodies of such high cohesive power, such as albumen. Brücke's view received important support from Voit and Bauer; in their experiments soluble albumen was not absorbed; but, when chloride of sodium was added, absorption set in. It rightly appeared to them improbable, that the conversion into peptone went on only under the influence of chloride of sodium. The results obtained by Voit and Bauer were completely established by Eichhorst. Thus in recent times the opinion that soluble albumen is absorbed as such, continues to gain adherents.

With regard to the absorption, there has been on every hand a change from the old opinion, that only the fatty acids and not the neutral fats are absorbed; and it is now firmly established, that fats are absorbed in the form of emulsion. This, however, holds good only for the small intestine. With regard to the large intestine, Bauer and Voit are inclined to the opinion that fat is not absorbed by the large intestine, although in their researches fat disappeared. According to Leube, fat is absorbed as such by the large intestine. Regarding the absorption of starch, it is generally assumed that it is converted into sugar before absorption.

In practical medicine, the question of absorption by the rectum is one of great importance. Partly to introduce medicines into the system, partly to increase impaired nutrition, use has for a long time been made of the absorbent power of the large intestine. Clysters, however, have been compounded in a rude and empirical manner, without any conception of the more minute processes; or, if they have been compounded on the basis of physiological views, they must fall under doubt as soon as the physiological views on absorption became changed. Without doubt, advantage is derived from clysters, which help the patient over a very transient disturbance of digestion, or which, once taken in, produce rapid stimulation, such as wine-clysters in acute conditions of debility. On the other hand, it

is still doubtful whether enemata administered by the rectum are capable of affording nutrition for a long period, although several such cases have been recorded. Thus, in a case of impermeable stricture of the œsophagus in a girl, Schultzen gave five times daily enemata of *bouillon* with egg, pepsin, and hydrochloric or lactic acid, the mixture being allowed to stand exposed to the sun until all was dissolved. Sixteen days before death, after the œsophagus was absolutely closed, the enemata were begun; in the last two days, they escaped unchanged. Runge nourished a patient by giving red wine and eggs by the rectum for fifty-four days. Leube started with the supposition that the large intestine does not digest, and introduced into the intestine nutritive material in a condition in which it was already capable of absorption. He supplemented the digestive power which was absent in the rectum by that of the pancreas, and obtained good results.

We made our researches on a man with preternatural anus (of the sigmoid flexure) in the left inguinal region. The case was distinguished from the others which have been employed for physiological investigation, in the circumstance that the rectum was completely exposed by the prolapsed loop of intestine; it could be filled from above with the articles of food on which the experiments were made, and, at any desired time, emptied *per anum*. As the rectum could be washed out from above like a retort, the discharge gave at once the amount of material absorbed. While Voit and Bauer deduced from the excreta, by an indirect process, the amount of water absorbed, we were able to directly determine the quantity of unabsorbed residue.

History of the Patient.—G. B. of H., aged 49, a strong waggoner, who was said never to have been seriously ill, had had left inguinal hernia for about five years. On February 18, 1873, the tumour in the scrotum was as large as a fist, and for some time past he had not been able to reduce it completely. He was now seized with severe pain, vomiting, and thirst, which led him to seek medical aid. As reduction could not be effected, and the symptoms of strangulation continued, herniotomy was performed on February 19, the sac being opened. The contents of the sac consisted of loops of intestine, which their size and the presence of longitudinal bands and transverse folds indicated to belong exclusively to the large intestine. One loop especially, appears to have been much distended and of a blue-grey colour. The intestines were attached to each other and to the walls of the sac by many adhesions, old and new; the attempt to break through these induced rather considerable hæmorrhage and was only partially successful; hence, the reduction of the hernia was impossible; and all that could be done was, to remove the cause of strangulation by dividing the neck of the hernial sac. After the operation, the pain and vomiting ceased; the abdomen, which had not been much distended, was soft and not painful on pressure. The patient had a quiet pulse and no fever. On February 21, sloughing took place in the prolapsed intestine and in the outer circumference of the operation-wound; and fæces were said to have escaped for the first time through the opening. The last evacuation *per anum* was reported to have taken place on February 17.

On February 22, the patient was brought into the surgical clinic. On his admission, there was seen in the left groin a swelling of the size of a fist, of a red colour, partly covered with shreds of sloughed

tissue. On making large incisions in the neighbouring skin, which was much inflamed, sanious matter containing gas, and having a fæcal odour, escaped. When the gangrenous portions of the integument had been thrown off, the swelling was recognised, by the sacculi and the longitudinal muscles, to be evidently a loop of large intestine about 25 centimètres (nearly 10 inches) in length when measured over the convexity, and surrounded at the base by the remains of the hernial sac. The intestine had been opened in three places; the descending limb at the neck of the hernia, the ascending about half way down, and there was a third opening at the greatest convexity of the loop.

On February 26, wandering erysipelas set in, and continued about twenty days; it was attended with high temperature, and the patient was in danger. After this had passed off, the serous surface of the intestinal loop and the surrounding extensive surface of the wound began to granulate, so that the longitudinal muscles and the sacculi, at first very distinct, gradually became indistinct. The serous surface of the intestine, which at first greatly exceeded in extent the exposed mucous membrane, contracted so greatly, that the edges of the mucous membrane of the openings gradually came into direct contact and were everted.

In July, the large cutaneous wound had become covered in with skin, and the three large mucous tumours corresponding to the three openings became confluent, forming one swelling covered with mucous membrane, marked by two deep furrows. From the uppermost opening projected a portion of intestine, which was about 11 centimètres (about 4½ inches) long, when the patient walked much. As the descending limb had been from the first completely shut off at the neck of the hernia, no fæces could pass into the lower portion of the intestine. The surgical importance of the case will be the subject of comment in another place.

Description of the Portion of Intestine used in Experiment.—For the purpose of experiment, we had the prolapsed loop with its two divisions, and the terminal portion of the intestine. The loop soon became so narrow, that there was difficulty in passing the little finger through it. Besides this, there was very remarkable contraction and shortening of the serous surface. There remained also for our purpose the terminal portion of the intestine below the lowest opening; this had retained its normal proportions. Its length was ascertained, by introducing a flexible tube into the rectum of the anus and bringing it out at the lowest fistulous opening, to be about 29 or 30 centimètres (about 11½ inches). As the circumference of the rectum in an adult man of the same age (undistended) is about eight centimètres (3.15 inches), there would be a surface of about 240 square centimètres, which with a radius of 1.28 centimètres, gave a space of 154.5 cubic centimètres. This agrees nearly with the result of filling the rectum with water from a height of forty centimètres (15.75 inches); from 180 to 210 cubic centimètres of water being poured in. The prolapsed mucous membrane was quite free from tenderness, and no contraction took place on irritating it with a needle or with the induced current. The constant current, on the other hand, produced, with two of Stöhrer's elements, active contractions, which continued as long as the electrodes were in contact with the intestine. When six elements were used, very energetic contractions followed, and the patient complained of colicky pains

in the abdomen, which were increased on multiplying the elements. The contractility was especially tested on the prolapsed portion of intestine, which reacted very readily. The contraction-wave was propagated from this very slowly to the perfectly separate exposed loop of intestine. The exposed loop also reacted very slowly to the constant current. Simple touch produced no contraction, even when pieces of ice were laid directly on the mucous membrane. On the other hand, when the mucous membrane was gently stroked by the finger or an instrument, contractions at once set in. This was especially remarked when the finger was passed into the lumen of the gut; the intestine at once contracted very strongly on it, and, if the exploration were continued longer, became red, and showed an increased secretion of mucus.

When the patient lay quietly in bed, the fæcal evacuations generally took place in the morning; but they showed similar irregularities to those observed in Busch's case. At night, as a rule, there was no evacuation of fæces. It was several times observed that, while the fæces passed from the uppermost fistulous opening, the contractions were not propagated to the lower portion of intestine. Antiperistaltic movements were not observed with certainty to be present. The exposed mucous membrane was normally of a clear red colour, but bluish red when inflamed, swollen, smooth (wrinkled during contraction), glassy, and firm to the touch. At first, while there were still some unhealed portions in the neighbourhood, the mucous secretion was tolerably abundant, and the thready glassy mucus could be collected in large drops without trouble. On the other hand, at a later period, when the experiments on absorption were made, mucus was present in smaller quantities only. The pure mucus was clear, soon becoming faintly opalescent, and contained scattered masses of protoplasm, somewhat larger or smaller than white blood-corpuscles; these generally presented nuclei, which were not always distinct, and were frequently covered with small fat-drops or contained small vacuoles. On slight irritation, epithelium generally became mixed with the mucus and produced distinct cloudiness. The mucus, as well as the mucous membrane, was intensely alkaline, and effervesced a little on the addition of an acid. The fæces generally had an intensely acid reaction.

Method of Research.—The researches were, in the first place, made on digestion and absorption. Digestion was tested by means of the intestinal secretion both without and within the intestine. Coagulated egg-albumen was placed with the intestinal secretion in test-tubes which, their mouths having been stopped with cotton-wool, were exposed for two or three hours to a temperature of 35° C. (95° Fahr.). The same was done with fat and with paste.

The changes within the intestinal canal were examined simultaneously with the researches on absorption. For the latter purpose, we used the terminal portion of the intestinal tract from the lower end of the sigmoid flexure to the anus. For the purpose of introducing the materials to be experimented on, the lowest of the fistulous openings, which led into the rectum, was used; a soft India-rubber tube, attached to a glass funnel by which the fluids could be conveniently poured in, was passed about 5 centimètres (4 inches) into the bowel. The last remains of the fluid were pressed out from the funnel and tube into the intestine. The fluids

were removed *per anum*, by means of an œsophageal tube. It was first ascertained what quantity of water could be contained in the portion of intestine used for experiment, without being forced out by its contractions. This was about 20 cubic centimètres; although under a somewhat higher pressure, as above-mentioned, much more could be introduced for a short time. It was further determined, how much water could be removed after its introduction *per anum*. In the first observations, there was a difference varying from 2 to 10 cubic centimètres, representing the quantity of fluid retained in the intestine.

The errors in investigation having been made as small as possible, the fluids to be experimented on were introduced every two hours into the rectum, in portions of 15 cubic centimètres, through the funnel and elastic tube.

In the process of removal, the fluid which was not absorbed was separately drawn off by the rectal tube. In order to further reduce as much as possible the errors which might be caused by the remaining of the fluids in the intestinal tube, the intestine was washed through the funnel and India-rubber tube with separate quantities of water, each 60 cubic centimètres, which were separately drawn off by the rectal tube, care being taken to remove each portion as completely as possible. As the weight of the water poured in was known, and the weight of the water withdrawn, after removal of the solid residue, could be ascertained, the difference between the water poured in and that drawn off represented the quantity retained in the intestine. Further, the condition and degree of concentration of the retained water must be the same as of that which last escaped. In the experiments with albumen and starch, water only was used for washing, but, in those with fat, a fluid capable of making an emulsion of the fat. The experiments were made with solutions of albumen, with the albumen of hen's eggs, with emulsion of fat, and with paste. The solution of albumen was prepared by beating ordinary egg-albumen with one and a half volumes of water, and filtering the mixture after it had stood for some hours, during which it was frequently stirred. Researches were also made with undiluted egg-albumen; this was beaten to a froth, and the fluid which remained was used. The fat was not taken directly as such, but an emulsion of olive-oil was used, prepared by adding a small quantity of carbonate of soda (0.5 per cent.) to the water. The paste had to be much diluted, so that it could be poured in as a fluid.

The fluids were subjected to accurate chemical tests before being poured in, and also after being removed. In the experiments with albumen, a weighed quantity was first evaporated to dryness in a water-bath, and then dried in the air at a temperature of 230° Fahr. until there was no further loss of weight. Another quantity of known weight was coagulated, and washed successively in a weighed filter with water, alcohol, and ether, and also dried at a heat of 230° Fahr., till there was no further loss of weight. In the later experiments, the filtrate of coagulated albumen was also tested quantitatively and qualitatively for the transformed albuminous compounds contained in it. The filtrate of the coagulum used in the quantitative analysis was evaporated in a water-bath, until traces of a solid residuum appeared at the edges of the fluid. (There was now only a small amount of the fluid remaining.) Absolute alcohol was then slowly added to the fluid in the water-bath, which was constantly

stirred, until a milky opacity had been produced. The warming of the fluid was continued until the precipitate had collected into large flocks which floated in clear fluid. The flocks were collected on a weighed filter, dried at a temperature of 230° Fahr., and weighed. The precipitate used for the quantitative determination was not fit for qualitative analysis, as the drying at a heat of 230° Fahr. changes the bodies so much that they no longer yield the reactions which they give when not dried. They also lose their solubility. A single test, therefore, was used for qualitative analysis. The albumen was prepared in the way above described, but instead of drying them after filtration at a temperature of 230° Fahr., the filter was left in a shady place, free from dust, until the alcohol had evaporated; a little boiling-hot water was then poured on the filter, and the resulting filtrate tested qualitatively. In consequence of the use of boiling-hot water, some of the albumen remains on the filter.

The chloride of sodium was determined by volumetric analysis with a solution of silver.

In the experiments with the fat emulsions, the dry residue was obtained by the use of a sand-bath over a very slow fire. For the direct determination of the fat, the ethereal extract of the dry deposit was used. Of the parts used, the dried residue alone was determined; this was also tested qualitatively for sugar. The acid or alkaline reaction of all the fluids was of course ascertained.

[To be continued.]

MAREY ON THE PHYSIOLOGY OF FLIGHT IN BIRDS.—In a recent note to the Paris Academy (*Comptes Rendus*, Jan. 12), M. Marey states that he has lately wrought in a new direction; trying, with mechanical arrangements, to produce wing-strokes capable of raising weights. He has succeeded in determining the conditions in which these apparatus can rise by the descent of their wings. It is necessary (he says), that the *moment* of the motive force be a little superior to that of the resistance of the air (the wings themselves being of negligible weight). The force was that of a spring attached near the articulation. The resistance of the air under each wing must be equal to half of the weight of the machine, in order to the effects of gravity being neutralised. If we suppose the wing of triangular shape, and the resistance of the air proportional to the square of the velocity, the point of application of the resultant of all the pressures of air under the wing will be situated in the middle of the wing, and at three-fifths of its length, reckoning from the joint. Thus it is easy to make an apparatus capable of rising by the descent of its wings. The necessary conditions are realised, when, placing a finger under each of the wings, at the points where the resultants of the air-pressures are applied, one can raise the machine without bending the depressing springs.

The author verified these dynamical conditions in nature; measuring the statical effort of which the pectoral muscles are capable, and determining their place of insertion, the form of the wings, and the bird's weight. When, however, he compared the velocity of wing-stroke of his apparatus with that observed in registering the movements of real birds, he perceived that the machine, in order to be raised, required a wing-stroke three or four times as rapid as that of the bird. Now, with equal motive

force, what governs the velocity of such motion is the resistance opposed to it; it seemed, therefore, that the air resisted his apparatus nine or sixteen times less than the wing of the flying bird.

M. Marey recoiled at the apparent absurdity of this conclusion; but from frequent measurements of the velocity of descent of bird's wings, he was convinced that it was insufficient to support the birds in the air, unless there were some condition present, increasing the resistance under the animal's wing, which was wanting in his apparatus. He endeavours to show that it is the translation of the bird that produces this increase of resistance; and his explanation is as follows.

The air, like all ponderable bodies, presents effects of inertia; that is to say, when subjected to a constant impulsive force, it resists strongly during the first instants, then acquires a velocity, and finally tends to maintain this velocity, when the impulsive force ceases. If we take a disc, and give it a uniform movement in a direction perpendicular to its plane, we may, with an inscribing dynamometer placed behind it, ascertain the resistance of the air at different instants of the movement. We then find, 1. a considerable resistance at the beginning; this is due to the inertia of the column of air which the disc tends to displace; 2. a weaker pressure, maintained during the movement; 3. a tendency of impulsion in the disc when it is stopped; this is due to the velocity acquired by the column of air in movement. Thus the resistance presented by the air to movements of a body is composed of a *regular regime*, preceded and followed by two *variable states*. The regular regime is what various experimenters have sought to measure.

If it be proved that, during the initial variable state, the resistance of the air reaches its maximum, then, clearly, the wing of a bird ought to find, in the air, a more solid fulcrum, if, during the whole time of its descent, it can place itself in these initial conditions. Now, through the bird's movement of translation, the wing, at each instant of its descent, acts on a new column of air which it tends to depress; but, owing to the short duration of the pressure, each of the air-columns has not time to acquire the velocity of the wing; it is compressed, and presents the maximum resistance of the initial variable state. To test this theory, the author gave his apparatus a horizontal movement of translation, and ascertained, in these circumstances, an increase of the resistance of the air to the wing's movements, shown in retardation of those movements.

Then he made an artificial bird, the wings of which were driven by an air-pump. A steam-engine working this pump uniformly, produced perfectly regular wing-strokes. The artificial bird placed at the extremity of a long arm could be made to beat its wings, either remaining in one place, or being subjected to a quick circular motion. Measuring the amplitude of the strokes when the apparatus was not rotated, M. Marey found that, between the two extreme positions, the wing formed an angle of about 60 degrees. With a circular movement of about 10 m. per second, the amplitude of the strokes fell to 30 and even 20 degrees. Now, there was no change in the motive force, or in the frequency of movements of the wings; it is necessary, then, to suppose an increase of the resistance of the air, to explain this diminution in the amplitude, that is, in the velocity of the strokes.

Thinking it possible that the centrifugal force

developed might be a disturbing influence, the author varied the experiment, giving the artificial bird a rectilinear movement, but the same retardation was obtained.

Several phenomena, it is pointed out, may, in this way, be explained. Thus when a bird takes flight, the movements of its wings are very expanded; but they are less so when the horizontal translation of the bird is become rapid. When a bird flies attached to a string, it descends (notwithstanding that the wing-strokes continue) whenever the tension of the string stops its horizontal velocity. A bird, in taking flight, turns towards the wind as much as possible; because then the wind, continually bringing new layers of air under its wings, places it in the same conditions as horizontal translation.

ALEX. B. MACDOWALL.

THERAPEUTICS.

ON CHLORAL-HYDRATE AND ITS USE IN MEDICINE. BY DR. OSCAR LIEBREICH, PROFESSOR OF MATERIA MEDICA IN THE UNIVERSITY OF BERLIN.*

The numerous new notices which have been published since the appearance of the third edition of my essay on Chloral-Hydrate (Berlin, 1873) induce me to return to this subject; although I had hoped that the explanations given in that work would be sufficient to place the indications for the use of this medicine in a more secure position. But, just as before, the most contradictory views multiply. Extolled by some, by others it has been altogether thrown aside, when used in the treatment of the same symptom. As far as my experience in most cases has taught me, this does not depend on uncertainty in the action of the medicine, but on the imperfect carrying out of the instructions which I have very distinctly given. I do not deny—on the contrary, I have emphatically stated—that there are certain contraindications to the use of chloral-hydrate: and the true value of a remedy can only be determined when these contraindications are most surely determined.

In most substances in use derived from the animal and vegetable kingdoms, the action is centred in one or more chemical bodies of constant composition. Technological chemistry knows how to obtain these by certain fixed methods; and apothecaries buy these substances for the purposes of dispensing, and are content to test their purity by chemical examination. Even if there be impurity, the principal action of the drug always comes into the foreground when it is administered, and can at most present changes of degree, not of kind.

The conditions are quite otherwise with substances which are obtained by the action of chemical processes on organic substances. Every one knows how small an addition of impurity is sufficient to render chloroform incapable of being used in medicine. Quinine, on the other hand, may contain other substances arising from the process of manufacture, without showing a dangerous or perverted action.

As with the preparation of chloroform, so with that of chloral, it is one of the most difficult technical operations to attain a preparation that shall answer

its therapeutic object. A great part of the cases observed by therapists have been treated with impure preparations; and I would not venture to make this assertion if I were not in a position to give ocular demonstration of it. I have not failed, in cases where there was a continuously bad action of the chloral, to have the preparations submitted to me; and thus I possess a collection of the most horrible chemical mixtures, which I should never venture to give to any man. The mode of preparing chloral has been no secret; it has been publicly described in a classical manner by Justus von Liebig. A few grammes were enough for him to perfect the discovery on chemical principles; so great a quantity as fifty grammes, which I delivered to the chemical discoverer of chloral, had, according to his statement, never been seen by him in one mass. If, in spite of ample directions, the preparation of a small quantity requires the hand of a practised chemist, it is easy to understand that the preparation of large quantities must seem at first quite impossible. After the publication of my therapeutic observations, it would perhaps have been some years before chloral hydrate was introduced into practice, had it not been perfectly clear to me that I must undertake the manufacture of the preparation under my own observation. Thus the first large supplies which came into the market were manufactured by Dr. Martius and Dr. Mendelssohn. Every one had now a standard for comparison; and soon manufactories of the preparation arose in the most various localities.

The mode of manufacture cannot be held responsible for the activity of the various preparations, in so far as the research into their fitness for use lies beyond the limits of chemical analysis. In many products the impurity is quite evident, and yet they have been allowed to be used by hundred-weights. In this way, it is possible to indicate districts of the country where chloral-hydrate has fallen into utter discredit through the badness of the products used under its name. In America, *inter alia*, gangrene has been observed after the use of chloral-hydrate. In the kingdom of Saxony,* where the drugs are mostly obtained from one establishment, the use of chloral has fallen into discredit; and in the druggist's shops in Switzerland I was told that they would no longer keep such a dirty substance as chloral, especially as the physicians there, after experience of its action, have quite given up its use.

Until lately chloral was used in the laminated form, prepared by distilling anhydrous chloral at a proper temperature with a sufficient quantity of water, and thus forming a hydrate of chloral. In such a mode of preparation, the correct boiling-point and the reaction necessary to purity can be accurately found, and even the amount of chlorine contained may be nearly correct; yet, in spite of this, hurtful substances are formed during the preparation or in consequence of the ready decomposition of the laminæ.

The foreign substances may be of two kinds. There may be substances containing chlorine, which form hydrochloric acid in contact with alkalis or even with water, and, as has been shown by experiments on animals, may cause death when used in relatively small quantity. Chloral-hydrate of this kind often has a good appearance, but is one of the most dangerous preparations; when it is given to man, the

* When chloral-hydrate was required for use in a high quarter, that prepared in Berlin had to be sent for, as the confidence in the local preparation was too much shaken.

* *Berliner Klinische Wochenschrift*, no. 5, 1874.

stage of excitement becomes excessive, and altogether overcomes the desired hypnosis. On the other hand, I have observed that the sleep-producing power of chloral-hydrate in laminæ may be more energetic than that of the perfectly pure hydrate. The reason of this lies in the admixture of such substances as, under decomposition, produce chloroform more rapidly than chloral does. I have, however, never as yet succeeded in forming this interesting mixture; and, as every chemist knows, the process of manufacture is so complicated, that it is impossible to determine what are all the products that result from the process. This last-mentioned admixture would not in itself be a disadvantage in the therapeutic use of hydrate of chloral, if it were constant; but, unfortunately, there is the uncertainty as to the dose to be given, and the danger, in changing the preparation, of giving at one time too much, and at another time too little.

There is one phenomenon to which I would recommend special attention, namely, that pure chloral-hydrate in laminæ suddenly undergoes alteration, generally with the expulsion of hydrochloric acid gas.

For the reasons here adduced, it became necessary to consider how to discover a form of chloral-hydrate which should give a guarantee of greater stability. The endeavour has been successful; and the crystals of hydrate of chloral obtained from the most various fluids, such as chloroform, ether, sulphide of carbon, benzol, &c., appear, when pure, to be altogether the most desirable preparation.

This form has been received into the German *Pharmacopæia*; but the mode of preparation is not sufficiently indicated, and consequently products in this form are brought into the market, which worthily vie with the worst specimens of laminæ. Setting aside the fact that the statement of the maximum dose has apparently been forgotten in the German *Pharmacopæia*, the description in that work is in no way sufficient for its use in medicine. It is but rarely that it can be obtained absolutely free from hydrochloric acid, even when the purest laminæ have been used for crystallisation; and the neutral reaction, under the slightest oxidation in the air, passes into acidity.

I have assigned to chloral the properties of freedom from hydrochloric acid and neutrality. But, in preparing the drug on an extensive scale, these cannot be equally obtained; and the German *Pharmacopæia* gives instructions on this point which go far beyond the limits of possibility. Chloral-hydrate, pure in other respects, may contain a large admixture of hydrochloric acid without any detriment to its action, though it cannot be used for analysis; in therapeutic use such a combination with hydrochloric acid may even appear desirable, and I shall have an opportunity of returning to this subject in the therapeutic part of this article. The evidence of the presence of hydrochloric acid in chloral does not show that the preparation is useless; but the constant formation of hydrochloric acid under the influence of decomposition by water indicates danger of impurity. . . . A solution ought to show no increased indication of the presence of chlorine within a given time. We may convince ourselves by examination, that many specimens of chloral, which at first give no evidence of chlorine, yet gradually yield chlorine and become unfit for use. Just as little is the acid reaction to be feared in an otherwise pure product. A solution of pure chloral becomes acid, by oxidation into trichloroacetic acid,

which delays its hypnotic action but does not change it. Impure chloral, through the formation of hurtful chlorinated compounds, which are evidently not trichloroacetic acid, manifests a constantly increasing acid reaction and a perverted therapeutic action.

The German *Pharmacopæia* gives the boiling-point of the crystals as about 95° Cent. (203° Fahr.). This is about the boiling-point of anhydrous chloral, while chloral-hydrate has no constant boiling-point.

I have thought it my duty to make these preliminary remarks in the interest of the use of the medicine. They show that, chloral being a substance of which little has been hitherto known, and the modes of preparing it being often rough, many apothecaries' shops, partly from ignorance, partly from mercantile views, furnish very bad products; the more so, as the directions given in the German *Pharmacopæia* afford no security for the purity of the drug.

(To be continued.)

PUBLIC HEALTH.

MEDICAL STATISTICS OF THE CENSUS.

The following highly valuable and important particulars with regard to the idiots or imbeciles, lunatics, and patients in hospitals in Great Britain, are extracted from the final report of the Census Commissioners, which has just been issued.

Idiots or Imbeciles.—In conformity with the terms of the Census Act, an attempt has been made for the first time to ascertain the number of idiots or imbeciles amongst the population of England and Wales. This has been done by means of an instruction in the householders' schedules, requiring that if any persons mentioned therein were suffering under the infirmity of idiocy or imbecillity they should be so described.

According to the returns, the total number of persons described as idiots or imbeciles in England and Wales is 29,452, the equality of the sexes being remarkable—namely 14,728 males and 14,724 females. Compared with the entire population the ratio is one idiot or imbecile in 771 persons, or thirteen per 10,000 persons living. Whether the returns are defective owing to the natural sensitiveness of persons who would desire to conceal the fact of idiocy in their families, we have no means of knowing; but such a feeling is no doubt likely to exist among those who look upon mental infirmity as humiliating rather than as one of the many physical evils which afflict humanity. As regards the distribution of idiots and imbeciles, the largest proportionate numbers are in the South-eastern division, which includes the Earlswood Asylum and other institutions containing persons of this class. The numbers are also above the average, in proportion to the general population, in the South-midland, Eastern, South-western, and West-midland divisions, and below the average of England in the London, Northern, York, and North-western divisions.

The ratio of idiots or imbeciles to the population in the several divisions was as follows:—London, one in 1,708; South-eastern, one in 518; South-midland, one in 641; Eastern, one in 636; South-western, one in 669; West-midland, one in 642; North-midland, one in 666; North-western, one in 833; Yorkshire, one in 901; Northern one in 1,028;

Wales, one in 739; England and Wales, one in 771.

Idiots and imbeciles seem to be the last class which has obtained the attention of philanthropists and men of science. Less has been done for them than for lunatics, partly because they are a less dangerous and troublesome class, but partly also from the doubt which existed as to the possibility of effecting a cure, or even any material alleviation of their condition. But attention has now been directed to them, and in consequence of the observation and experience of the last twenty-five years it has been ascertained that in a large proportion of cases of congenital mental infirmity a patient may, by care and training, be made able to contribute, at least in part, to his own support. This and other important results have been accomplished by the means of the special institutions established for these unfortunate persons. At the time of the census there were 3,456 imbeciles—1,998 males and 1,458 females—in special asylums for this class or in lunatic asylums. This is in the proportion of 1 in 8·5 of the whole number. In the south-eastern division the proportion in asylums was one in three, in the Welsh division one in eight, in the west-midland and North-midland divisions about one in nine, while in London only one in sixteen, and in the North-western and Northern divisions about one in seventeen, were in asylums. Those not in asylums were chiefly in workhouses, which contained 7,976 imbeciles, of which 3,548 were males, and 4,428 females.

A valuable institution for the benefit of this class, the Asylum for Idiots at Earlswood, Redhill, Surrey, was instituted in 1847, and incorporated by royal charter in 1862. This important establishment contained 510 inmates 342 males and 168 females at the date of the census. During the year 1872 the average number of inmates was 553. The most beneficial results have followed the efforts made on behalf of these comparatively helpless persons, a large number of whom are usefully employed. As the institution has no funded property whatever, the large sum of 16,000*l.* has to be raised annually by voluntary contributions for maintaining its successful operation.

Two important institutions, situated respectively at Caterham in Surrey, and Leavesden, near Watford, Herts, have been established under the managers of the Metropolitan Asylum District for the reception of harmless chronic lunatics and imbeciles chargeable to the several unions and parishes of the metropolis. These buildings were opened in 1870, and were soon fully occupied by the transfer of the imbecile and lunatic paupers from the workhouses in which they were previously maintained, or from the county lunatic asylums to which they had been removed. At the date of the census there were in the Caterham Asylum 511 male and 755 female patients, total 1,266; and in the Leavesden Asylum 716 male and 875 female inmates, making a total of 1,591. In these asylums, as at Earlswood, measures are taken for supplying opportunities of employment, and of recreation to the patients.

| | Total of Idiots and Imbeciles. | Males. | Females. |
|---------------------|--------------------------------------|--------|----------|
| Under 5 years . . . | 428 | 210 | 218 |
| 5 and under 20 . . | 7,447 | 4,196 | 3,251 |
| 20 " 60 . . | 17,435 | 8,512 | 8,923 |
| 60 and upwards . . | 4,142 | 1,810 | 2,332 |
| Total . . . | 29,452 | 14,728 | 14,724 |

From the tables showing the ages of persons labouring under defect of brain power, it appears that relatively to the general population of the respective ages, the ratio per 1,000 is 1·6 between the ages of twenty and sixty, and 2·4 at sixty and upwards.

To the age of thirty the males preponderate; after that age there is a considerable excess of the other sex.

The principal causes of idiocy and imbecillity are spoken of by those who have studied the subject as distinctly recognised; they are connected with physical or mental weakness, or with abnormal conditions, either the fault or the misfortune of parents. Residence in deep valleys, damp and unwholesome climate, crowded dwellings or other unhealthy conditions, intermarriages among a limited number of families, and more especially where weakness of brain already exists—these are allowed to be predisposing causes; and as they are obviously within human control, the hope may be entertained that the extent of this affliction may be limited in the future.

Lunatics.—Precisely the same measures were taken to ascertain the number of the insane in England and Wales as those already described with reference to idiots. The result is that 39,567 persons—18,146 males and 21,421 females—were returned as insane at the time of the census, being in the proportion of one in every 574 of the general population.

In the report on the census of 1861 we were enabled to give only the number of inmates in the principal lunatic asylums and other establishments for the reception of the insane, namely, 24,345 persons—a great increase upon the number in 1851, which was 16,426 persons. This increase was explained chiefly by the fact of the removal of pauper lunatics from union workhouses to county lunatic asylums, partly by the discovery of fit objects for treatment previously unnoticed, and partly by the supposed prolongation of their existence when thus brought under care. The present returns show an increased number of lunatics in asylums—namely, 35,790 of both sexes—16,545 males and 19,245 females; and the increase must be mainly attributed to causes similar to those in operation between the censuses of 1851 and 1861.

It is a very interesting social question, and one of the utmost consequence to the community, whether mental disease is gaining ground amongst the people of this country. The materials for arriving at a satisfactory solution of this question appear to be wanting. From the returns published in the reports of the Commissioners in Lunacy, it appears that an increase in the absolute number of the insane upon the register is yearly taking place, and that there is also an increase in proportion to the population. On January 1, 1861, the total number of lunatics, idiots, and persons of unsound mind on the Commissioners' register was 39,647, and on January 1, 1872, the corresponding number was 58,640, the ratio to 1,000 of the population having increased from 1·97 to 2·54; but much of this increase must be ascribed to improved registration, to wider recognition of the advantages of asylums, and to a diminished rate of mortality amongst the insane and imbecile in well-regulated establishments specially adapted for their protection and treatment. Formerly the friends and relatives of persons suffering from mental infirmity kept them at home as long as it was safe to do so, because they associated the lunatic asylum, or 'madhouse,' with

the idea of ill-treatment or neglect; whereas now, owing to the increasing confidence felt in the humane treatment of the sufferers from mental disease, the first thought of the relative is to send the patient to an asylum, where they know he will have a certainty of careful attention and the best chance of recovery. The aggregate return of lunatics, idiots, and imbeciles at the census is 69,019, while the Commissioners in Lunacy had on their register on January 1, 1871, only 56,765 'lunatics, idiots, and persons of unsound mind'; so that there might be a large addition to the registered number without a corresponding increase of new cases. Upon the whole, notwithstanding an impression to the contrary, we think that an increase of persons afflicted with mental disease cannot from the facts before us be assumed to have taken place among the population of England and Wales.

Of the 69,019 lunatics and imbeciles returned at the census, more than two-thirds were chargeable to the poor-rates under the denomination of insane paupers. The following is the official return of 'insane paupers' on 1st January, 1871:—

In county or borough lunatic asylums, 27,534; in registered hospitals or licensed houses, 2,741; in workhouses, 10,877; residing with relatives, or in lodgings, or boarded out, 7,292; total, 48,444.

With respect to this return it is stated that it 'includes a large proportion of persons imbecile from old age and of harmless idiots;' the distinction between the idiotic and insane is not observed in the statistics of Poor Law relief.

According to the returns of the Commissioners in Lunacy the total number of lunatics, idiots, and persons of unsound mind registered on the 1st January, 1871, was 56,755 being in the ratio of 2.49 per 1,000 of the population, and they were thus distributed; in county and borough lunatic asylums, 28,979; in workhouses, 12,161; in registered hospitals and licensed houses, 7,078; in naval and military hospitals and Royal India Asylum, 354; in Broadmoor Criminal Asylum, 460; residing with relatives or others, 7,723. The total of 56,755 is made up of 6,110 private patients, 50,185 paupers, and 460 criminals. With respect to workhouses, the Commissioners are able to exercise only a limited control over the arrangements for the comfort and proper care of the insane inmates. The power given by a recent statute for the removal to asylums of patients thought unfit to be kept in a workhouse is said to have proved to be a most salutary provision; but the Commissioners state that they are still without direct power to remedy defects they may notice in these establishments, or to enforce the carrying out of the measures suggested by them for securing improved accommodation for the insane. The first experiment of providing institutions intermediate in character between the workhouses and the county asylums for the reception of harmless chronic and imbecile cases has been successfully carried out at Leavesden and Caterham. On December 31, 1871, there were in England and Wales 54 county and borough lunatic asylums, 16 registered hospitals, 4 state asylums, and 106 licensed houses, making 180 establishments for the reception of the insane, exclusive of about 300 private houses, each containing a single patient.

The local distribution of the 39,567 persons returned as insane at the census depends very much upon the situation of the county and borough asylums and other large establishments for the reception of this class. In some instances two or more adjoining

counties have combined to maintain one asylum. The proportion of lunatics, exclusive of persons described as idiots or imbeciles, to the population is highest in the South-midland division, which includes the Hanwell, Colney Hatch, and other large asylums; the South-eastern, South-western, Eastern, and West-midland divisions follow next in order. In the more northerly divisions and in Wales the proportions are much lower, and in London, although it contains several large asylums, the ratio is lowest of all.

It is clearly shown by the returns that, while cases of idiocy are somewhat more frequent amongst males than females, insanity is more common amongst females than males, and in a marked degree. The 18,146 male lunatics and 21,421 female lunatics returned at the census are in the proportion of 16.4 males to every 10,000 of the male population, and 18.4 females to every 10,000 of the female population of England and Wales. These facts do not support the hypothesis which has been advanced that the greater activity of brain demanded now-a-days from men engaged in commercial and professional pursuits, and the nature of the toil of large bodies of workmen congregated in towns and cities, tend largely to produce an increase of mental disorders; for if this were true, the returns would not show a large excess of cases of insanity amongst women.

As regards the ages of the persons returned as lunatics, the abstracts furnish the following results.

| | Total. | Proportion per cent. |
|-----------------------------|--------|----------------------|
| Under 20 years . . . | 1,042 | 2.6 |
| 20 and under 40 years . . . | 14,166 | 35.8 |
| 40 " 60 " . . . | 16,739 | 42.3 |
| 60 " 80 " . . . | 7,179 | 18.2 |
| 80 and upwards " . . . | 441 | 1.1 |
| Total . . . | 39,567 | 100.0 |

The excess of females suffering from insanity commences at early periods of age. The large proportion of the insane at advanced ages above sixty, points to the success of the means taken for the prolongation of life in the case of chronic incurable lunatics as well as others.

As this inquiry has revealed the fact that there were no fewer than 69,019 insane or imbecile persons in England and Wales at the time of the census, we may remark that there is perhaps no social problem which demands greater attention than how to prevent the growth of mental disease amongst our population. The theory that insanity is a product of civilisation, and that it has been increased by the spread of education among the masses, is entirely unsupported by evidence. The statistics of lunacy fail to show any increase of insanity amongst the ranks in which the mental powers have of late years been so much more cultivated and exercised than formerly. On the other hand, amongst the poorer classes there is an increase in the number of persons under supervision and treatment for mental maladies. This increase has been so marked during the last two years as to have suggested the idea that the explanation is to be found in higher wages, and the consequent means of undue indulgence afforded to some of the working class; while others, by the operation of the laws of supply and demand, have been reduced to the direst poverty and distress.

It has been established by the observation of many authorities that intemperance is the most prolific cause of insanity, especially among the working

classes. To the cases of madness resulting from habits of drunkenness on the part of the individuals themselves must be added the numerous instances in which persons owe their insanity to the intemperate habits of their parents. It is said that the fruitful source of mental disease, hereditary taint—insanity inherited from parents—is fostered by the insane being allowed to propagate their kind with scarce any effort to check so deplorable an event. Large numbers of the insane and the idiotic still remain at home or are 'boarded out,' and become in many instances the agents of extending the fell malady through their offspring.

The following are the absolute numbers and the proportions to the general population, at vicennial periods of age :—

| | Under 20 Years of Age. | 20-40 | 40-60 | 60-80 and up- wards. | 80 |
|---------------------|--|-------|-------|-------------------------|----|

Patients in Hospitals.—Following the course adopted in 1851 and 1861, we have caused abstracts to be prepared showing the number, sex, and ages of the inmates of hospitals for the sick, and of prisons. The principal results presented in these tabular statements will now be briefly noticed.

Since the previous census a large amount of additional hospital accommodation has been provided in the cities and towns of England; in several villages 'cottage hospitals' have been established; and it may be truly said that there is scarcely any form of bodily suffering to which the doors of one or other of these institutions is not open. The hospitals—sometimes called infirmaries—are chiefly of three classes: general hospitals, in which are received as in-patients or treated as out-patients persons suffering from diseases (with certain exceptions), accidents, injuries, and deformities; special hospitals for patients suffering from one class of diseases, as fever, small-pox, or consumption, and class hospitals which receive only one description of persons, as soldiers, sailors, women, children, &c.

The number of in-patients under treatment in hospitals of these several kinds (excluding the sick wards of workhouses, prisons, &c.) on the day of the census was 19,585, namely, 11,425 males and 8,160 females. In 1861 the number of in-patients in the civil hospitals (the military and naval hospitals not having been included in the tables) was 10,414. Some part of the greatly augmented number of sick persons in hospitals on April 3, 1871, was owing to the severe epidemic of small-pox then prevalent, which appears to have killed in England and Wales, within the year, upwards of 23,000 persons. In the hospitals for small-pox under the Metropolitan Asylum Board, situate at Homerton, Stockwell, and Hampstead, 12,840 patients were admitted during the year, of whom more than one-sixth died. The aggregate number of the sick in hospitals gives the ratio of 1 in 1,160 of the general population.

The highest ratio of the sick in hospitals is found in London, where twenty-five males and twenty-one females in every 10,000 of each sex were in-patients. Considerably more than one-third of the total number returned were in these hospitals, whither patients are attracted by the high reputation of the medical officers, the extent of the accommodation, and the immediate attention that is given in cases of accident and emergency. Next to the metropolis the in-patients were most numerous in proportion to population in all the south-eastern counties, and in Devon, Gloucester, and Warwick. They were proportionately least numerous in the Welsh statistical division.

The abstracts of the ages of the sick in hospitals present the following aggregate results :—

| | Total. | Proportion per cent. |
|---------------------------|--------|-------------------------|
| Under 10 years | 2,203 | 11.2 |
| 10 and under 20 | 4,617 | 23.6 |
| 20 " 40 | 8,187 | 41.8 |
| 40 " 60 | 3,226 | 16.5 |
| 60 " 80 | 1,228 | 6.3 |
| 80 and upwards | 124 | .6 |
| Total | 19,585 | 100.0 |

The children under ten in hospitals were more than double the number enumerated in 1861. At all the age periods to sixty-five years the males preponderate.

As powers are now given by statute enabling every sanitary authority to provide, within its district, hospitals or temporary places for the reception of the sick, a further extension of the hospital accommodation may be expected, and the means will no doubt be provided to secure the isolation of cases of dangerous infectious disease in localities where no such provision has hitherto been made.

SANITARY OPERATIONS AT CROYDON.—The mortality tables of the parish of Croydon for the year 1873, as compiled by Dr. Westall, have been issued. The comparative mortality has generally shown the parish of Croydon to be nearly as healthy as the country districts; for the last year, however, Croydon has earned the distinction of being absolutely healthier, not merely than the town districts of England, and the average of all England, but of the country districts exclusively. In the town districts of England the mortality during last year was 23.2 per thousand; in the country districts, 18.5; in all England, 21.2; and in the parish of Croydon 17.4. The total number of persons who died in Croydon in 1873 was 999 against 1,040 in the previous year. Of the 999 deaths there were none from cholera, two from dysentery, five from small-pox and nine from fever, four of the latter occurring at Norwood. Croydon was one of the first towns in the kingdom to adopt the principle of sewage irrigation, and, as the result of this and an improved system of sewage ventilation, the effects of epidemic diseases are found to be much less severe than formerly, and the death-rate has diminished till the average has become lower than that of the most favoured country districts.

SANITARY INSPECTOR'S REPORT, MADELEY UNION.—Some admirable printed reports made by the Sanitary Authority of the Madeley Union, the Inspector of Nuisances, Mr. C. Slagg, are before us. Sanitary surveys of villages by competent persons have long been wanted. Those of Madeley and

Coalport, the parish of Little Wenlock, the Dawley district, and the parish of Much Wenlock are models of what should be done throughout the country. The sanitary defects are of course numerous. They are well considered under the following heads :

1. Exhalations of privy cesspools, and how to prevent them.
2. Exhalations of drains and sewers, and how to prevent them escaping into the air daily breathed by the inhabitants—that is, the air at or near the ground.
3. Contaminations of the sources of water supply.
4. Dampness of floors upon which, and the walls against which, people lodge ; and whether the rain-water which falls upon the roofs of houses, and other buildings, is caught and stored for use.
5. Whether the trades of the town are carried on so as not to be a nuisance.
6. The keeping of pigs near to dwelling-houses.
7. The house drainage and the sewage.
8. The disposal of the sewage that must necessarily flow from the house down to the outfall of the sewers.

Not only have these matters come within the province of Mr. Slagg to report upon, but he has done what very few have been so well able to do, that is, to give in a very lucid and practicable manner the remedies most easy of attainment and so far render to Boards of Guardians and to Medical Officers of Health a more easy task than many of them find themselves in a position to perform. In regard to pig-sty nuisances, Mr. Slagg thinks it more a question of attention to the cleaning out of the sty than of distance from a dwelling-house. He very properly fixes no arbitrary distance ; but if near and badly kept they must be considered a great nuisance. They cannot be kept in a proper condition if paved roughly with boulders or rough bricks. All pig-sty floors should be evenly paved, so that filth can be easily swept out. The following is admirable advice. All water should be excluded from privy cesspools, and they should be converted into dry cesspits.

The reports of Mr. C. Slagg are all extremely interesting and instructive to Officers of Public Health, and more so when we consider that the new class of men coming forward have much to learn.

R. HARDWICK, M.D.

ADULTERATION OF FOOD ACT : PROSECUTIONS.
At the Worship Street Police court, two shopkeepers were fined for selling adulterated butter. In one case it was proved that the butter had been adulterated with nearly 21 per cent. of water ; in another, where the seller, after having been paid for it, said she could not recommend it, it was stated that there was a large adulteration by tallow as well as a quantity of water, so that the composition was heavy against the purchaser. In the latter case a fine of 10s. and 12s. 6d. costs was inflicted.

MISCELLANY.

VACCINATION IN RUSSIA.—An imperial edict in Russia requires that *employés* in hospitals, barracks, and prisons, should be taught how to vaccinate, and should vaccinate all the individuals under their supervision.

CONTAGIOUSNESS OF SCARLATINA.—Dr. Snow, the Health Officer of Providence, Rhode Island, in his monthly report, uses this language with reference to scarlet fever. 'I have seen no reason, in the present epidemic, to change the opinion formed from twenty years' close observation, that it is not contagious in the ordinary meaning of the word.'

AMPUTATION WITHOUT HÆMORRHAGE.—A case of amputation without hæmorrhage is reported in the *American Journal of the Medical Sciences*, by Dr. E. P. Sale, where nature provided against bleeding in her own way. The patient, while chopping wood, nearly cut off his foot at the tarso-metatarsal articulation. He suffered so much from shock and hæmorrhage that amputation was postponed a week, when the part of the foot beyond the wound became gangrenous. Amputation was performed just above the ankle ; no hæmorrhage followed the operation. The patient recovered without an unfavourable symptom. It was accounted for by thrombosis of the various arteries, brought on by anæmia, which rendered the blood hyperinot, as in the formation of heart-clot after a profuse *post partum* hæmorrhage.

THE MEDICAL OFFICERS OF THE ASHANTEE EXPEDITION.—The war with Ashantee is now apparently at an end, with a much less considerable loss of life than was reckoned on ; the gallantry and endurance of a small army that has fought its way under a tropical sun, quite indifferent to fatigue and hard labour, is worthy of admiration. As a profession, we may also congratulate ourselves on the excellent feeling that has prevailed throughout the war between the medical staff and the executive ; indeed it has rarely happened that so great cordiality of feeling has existed, and we may attribute it very much to the voice of the medical officers being more listened to and respected than usual, in all that concerns health provisions. Judging by the despatches of the fall of Coomassie and return to the coast, Sir G. Wolseley and Commodore Hewett have had every reason to approve of the doings of the medical staff, of whom not less than eleven are mentioned by name for their excellent services ; and one we are proud to see pointed out by his commanding officer for an act that will doubtless secure to him the Victoria Cross 'for his gallant conduct in bringing in a wounded marine, at great personal risk, while the rear-guard was being attacked,' and of course immediate promotion will be given to so deserving an officer, as an encouragement to the young medical officers of the service to which he belongs.

THE MASSACHUSETTS DENTAL SOCIETY have resolved, almost unanimously, that the use of chloroform in dental operations is unadvisable.

USE OF ETHER FOR ANÆSTHESIA.—Since the introduction of ether as an anæsthetic it has been used in the Massachusetts General Hospital in 15,000 cases, with an average of half a pound to a patient. In one case four and a half pounds were used in twelve hours.

PROFESSOR HYRTL, who has taught anatomy in the University of Vienna for thirty years, is about to retire on account of failing eyesight. In recognition of his valuable services to science he is to receive 3,150 florins (about 315*l.*), and a yearly pension of 525 florins (about 52*l.*)

POPULAR SCIENCE AT THE ZOO.—The Zoological Society of London are taking laudable measures to extend something of scientific interest in their splendid collections among the great crowd of Londoners who visit the gardens to admire and wonder at the occupants of the cages, and the tanks, and at each other. They have arranged to commence forthwith a series of short courses of lectures of a popular character by eminent authorities. Mr. P. L. Selater, F.R.S., the Secretary to the Society, will deliver the Introductory Address on April 14; and he will follow it by four lectures, *On the Geographical Distribution of Mammals*. After these Mr. A. H. Garrod, the Prosector to the Society, will give five lectures *On the General Classification of the Vertebrata*; and Dr. Carpenter, F.R.S., will conclude the course by giving two *On the Aquarium and its Inhabitants*. The lectures will be delivered on the Tuesdays and Fridays in April and May, at 5 o'clock in the afternoon, they will be free to Fellows of the Society and their friends, and to other visitors to the Gardens. The attendance of ladies is invited.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers. Annual Subscription, 1*rs.* 4*d.*; free by post, 1*rs.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 1*rs.* 6*d.* Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The London Medical Record.

WEDNESDAY, MARCH 18, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BELLINI ON THE ACTION OF IODIDE AND BROMIDE OF MERCURY.

In a paper read on February 8 before the Medico-Physical Society of Florence, Professor Bellini thus sums up the results of experiments on the action of the iodides and bromides of mercury (*L'Imparziale*, March 2).

1. The iodides and bromides of mercury are more or less converted into double salts in the intestinal canal.

2. The reagents which produce this change are, in the stomach, the alkaline chlorides, lactic and hydrochloric acids, and protein aliments, vegetable as well as animal; in the small intestine, the chlorides, and the alkaline carbonates in the enteric juices.

3. The above-mentioned reagents, especially the alkaline chlorides, do not all act with the same energy as the iodides and bromides of mercury; a smaller quantity of double salts of mercury is produced with the protiodide than with the protobromide, and less with the latter than with the iodide or bibromide of mercury.

4. In the large intestine, the iodides and bromides of mercury, and the double salts arising from their decomposition, remain free and unchanged in suckling infants; while in children who are not suckling, and in adults, they are transformed into sulphides by the hydrosulphuric acid gas which is normally contained in this part of the bowels.

5. The iodides and bromides of mercury, applied to healthy or diseased external parts, or injected into the subcutaneous areolar tissue, are partly changed into double salts, principally by the chlorides with which they meet.

6. It is as double salts that the mercurial iodides and bromides act both locally and on the general system.

7. Thus the iodides and bromides of mercury are subject in the animal organism to the same changes as calomel, varying only in degree.

8. Sulphur, and the alkaline hyposulphites, when taken during digestion along with the mercurial iodides and bromides, paralyse the action of the latter: this is the result of the hydrosulphuric acid gas which is given off in the whole alimentary tract.

9. This action is also paralysed in cases where there is an abnormal development of hydrosulphuric acid gas in the intestinal canal.

10. Milk, richly seasoned diet, the alkaline iodides, bromides, and sulphites, ammonia and its salts, and cherry-laurel water, but not the alkaline hydrosulphites, provided that they are taken during fasting,

increase the local and general effects of the iodides and bromides of mercury.

11. These effects are increased, when the mercurial iodides or bromides are administered to persons in whose alimentary canal there is an abnormally large amount of ammonia.

12. Magnesia, in the form of hydrate or of carbonate, given at the same time with the mercurial iodides or bromides, does not destroy their effects, but rather increases them.

13. Acid drinks, food, and fruit, very probably increase the effects of the mercurial iodides and bromides, especially when they are taken some hours after the administration of these remedies.

14. The local and general effects of the iodides and bromides of mercury are greater when they are applied to healthy or diseased external parts, or injected into the subcutaneous areolar tissue, in individuals to whom the alkaline iodides, bromides, sulphites, or hyposulphites, are at the same time given internally.

15. The local and general therapeutic effects of these mercurials may, however, be absent when they are applied to ulcers or wounds in individuals who make use of alkaline hyposulphites; because the latter, in passing by osmosis from the blood with which they circulate into the morbid secretions, may be decomposed by the acids which are formed there, and then hydrosulphuric acid may be formed at the expense of the sulphur which is precipitated, and may reduce the mercury to the state of sulphide.

16. Sulphur baths should not be given when inunction with ointment of mercurial iodides or bromides is used, inasmuch as it paralyses their action, and produces more or less severe local irritation.

17. Clinical observations and experiments on animals are in complete accord with the results of chemical experiments.

In the discussion which followed the reading of Dr. Bellini's paper, Professor Schiff observed that, while it was impossible to deny the intrinsic value of Dr. Bellini's experiments, the results would be more conclusive if the experiments were made not only on rabbits, as Dr. Bellini had done, but also on dogs; inasmuch as rabbits and dogs, as far as regards digestion, represent two extremes, between which stands man.

A. HENRY, M.D.

DUMERIL, VERNEUIL, AND OTHERS, ON NASO-PHARYNGEAL POLYPI.

A recent lecture by M. Dumeril, of Rouen, brought on a discussion in the Surgical Society of that city, on naso-pharyngeal polypi, of which we reproduce the most important lessons (*Journal de Médecine et de Chirurgie pratiques*).

Some of the speakers had studied the nature of these tumours, but some differences arose, since it seems that the nature of tumours referred to polypi of the pharynx is far from being unquestionable. Thus we often meet with sarcomata or fibro-plastic cancers, which are said to be polypi; whilst on the other hand we find polypi of a fibrinous appearance, sometimes with mucous prolongations, which perfectly simulate naso-pharyngeal polypi. The absence of hæmorrhage constitutes one of the greatest dissimilarities from the last-mentioned tumours. This is a most important clinical fact, since hæmorrhage has a large share in the exhaustion and death of patients.

Moreover, their implantation frequently occurs at

the posterior orifice of the nasal fossæ, instead of at the basilar apophysis. MM. de Saint-Germain and Panas cited some interesting facts on this point.

M. Panas, who has made anatomical researches in this region, calls attention to the fact that there is in this situation a mucous membrane with a thick fibrous lining, favourable to the development of this lesion. These polypi, however, are easy to be operated on either with or without incision of the soft palate, by tearing away or even by excision with the scissors. Notwithstanding some cases reported by M. Verneuil, the majority of the members of the society did not admit the existence of naso-pharyngeal polypus in women, or in individuals who have arrived at maturity. It is a disease of youth. When it is met with under other circumstances, it shows us that we have to deal with tumours of another kind, frequently cancerous, and with fibromata having another origin than the basilar apophysis.

Such is the opinion expressed by M. Dolbeau. Other speakers, amongst whom M. Verneuil was prominent, thought this an exclusive opinion; as we do not know definitely the limit of naso-pharyngeal polypus. It possesses no peculiar characteristics beyond hæmorrhage, hardness, and mode of implantation, and even these do not exclusively belong to it. However that may be, it is important to recognise this tumour, which some practitioners have declared to be incurable, now that powerful means can be employed against it. It results from this discussion that, even if rapid recurrence be the rule, cure may be obtained by prompt and successive destructions of new growths; also, as the individual grows older, the tumours show less tendency to recur or to increase, so that cure has been known to supervene after partial destruction. Even M. Guyon's important observations seem to demonstrate that the majority of patients cured retain a sort of thick, fibrous, and abnormal cushion on the basilar apophysis. In such cases M. Verneuil does not believe that we are justified in ranking them as complete cures. If hæmorrhage be the principal characteristic of naso-pharyngeal polypi, the facility with which they reproduce themselves is still admitted by the majority of speakers in such a manner that many of them, like M. Dolbeau, almost absolutely reject the operations of temporary resection that have been proposed, in which the whole or part of a bone is displaced to pull away the polypus and cauterise the pedicle; the bone being immediately restored to its position. Most surgeons will find it necessary to repeat the cauterisation promptly and frequently on the basilar apophysis, if it be desired to avoid recurrence. Amongst the most highly recommended operations are those which consist in dividing the soft palate at the median line with either a bistoury, scissors, or the galvanic cautery; in removing the polypus by the *écraseur*, the galvanic cautery, by crushing, or even by excision, and in cauterising the point of implantation vigorously during some months if necessary. There is no need to trouble oneself about the cleft in the palate; it closes spontaneously, and even more quickly than is desirable. A perfect cure cannot be guaranteed until after many years' observation. Some of the speakers were particularly fearful of hæmorrhage. M. Demarquay related a very remarkable occurrence respecting a woman from whom he had removed the superior maxillary bone. Some blood escaped into the left bronchia. The patient became cyanosed and expired suddenly during the operation. This fact should be carefully noted as showing the

serious import of hæmorrhage. M. Guyon spoke of electrolysis, or the application of the electric poles into the tissue of the tumour. By combining this process with partial excisions, he has obtained excellent results, especially in the case of the son of a medical man whom he has kept in view for several years. Temporary resections were not very warmly defended. M. Chassaignac reminded the meeting that he had praised the merits of the nasal method (lateral and perpendicular incisions, allowing the nose to be thrown over on one side of the face) by which a large and easy passage is obtained for the *écraseur*. He asserted that he originated this method which had been borrowed from him by MM. Boeckel and Bruns; a fact which has also been categorically stated by M. Verneuil.

M. Chassaignac laid stress on the employment of the *écraseur* as a preventive against hæmorrhage. M. Ollier gave some account of his practice, in which he had operated on eighteen cases; of these two died, and about half were thoroughly cured. M. Ollier extolled a method of temporary resection invented by himself. It consists in circumscribing the upper portion of the nose from the ala to the root by a horseshoe-shaped incision, detaching the bones from the nose by a stroke of the saw, and turning the whole downwards; the strip of flesh and the bony structures being replaced after the extraction. Cure is rapid. The passage is narrow, but, having been constantly enlarged by the polypus, it is sufficient. He seizes the polypus firmly with the forceps and twists it on itself to draw it out. He has very little fear of hæmorrhage, never having lost a patient from that cause, but he operates very quickly by vigorous traction, and thoroughly scrapes the basilar apophysis. This is the only way not to leave any nucleus for the reappearance of the tumour. This contingency rarely occurs after the employment of this method, and if it should, the passage can be reopened by the same operation, which is simple, rapid, and leaves no visible traces. The two patients whom M. Ollier lost had prolongations of the polypi into the cranial cavity.

FERRIER'S FURTHER RESEARCHES ON THE BRAIN.*

In a paper read before the Royal Society on March 5, Dr. Ferrier gave the results of an experimental investigation, tending to prove that there is a localisation of function in special regions of the cerebral hemispheres.

In a former paper published by the author in the *West Riding Lunatic Asylum Medical Reports*, vol. iii. 1873, the results were given of experiments on rabbits, cats, and dogs, made specially for the purpose of testing the theory of Dr. Hughlings Jackson, that localised and unilateral epilepsies are caused by irritation or 'discharging lesions' of the grey matter of the hemispheres in the region of the corpus striatum. Besides confirming Hughlings Jackson's views, the author's researches indicated an exact localisation in the hemispheres of centres or regions for the carrying out of simple and complex muscular movements of a definite character, and described by him as of a purposive or expressional nature.

* *The Localisation of Function in the Brain.* By DAVID FERRIER, M.A., M.D., M.R.C.P., Professor of Forensic Medicine, King's College, London. Communicated by J. BURDON SANDERSON, M.D., F.R.S., Professor of Practical Physiology in University College.

Facts were also recorded tending to show that other regions of the brain were connected with sensory perception, but no localisation was definitely arrived at.

Among the experiments now related are some in further confirmation and extension of those already made on cats, dogs, and rabbits, as well as a new series of experiments on other vertebrates. In particular, numerous experiments on monkeys are described, for the purpose of which the author received a grant of money from the Council of the Royal Society. In addition, the results of experiments on jackals, guinea-pigs, rats, pigeons, frogs, toads, and fishes are narrated.

The method of investigation consists in the application of the stimulus of an induced current of electricity directly to the surface of the brain in animals rendered only partially insensible during the process of exploration—complete anæsthesia annihilating all reaction. It is supplemented by the method of localised destructive lesions of the hemispheres.

Special attention is called to the precision with which a given result follows stimulation of a definite area; so much so, that, when once the brain has been accurately mapped out, the experimenter can predict with certainty the result of stimulation of a given region or centre. The theory that the phenomena are due not to excitation of cortical centres, but to conduction of the electric currents to basal ganglia and motor tracts, is considered as disposed of by the fact of the precision and predictable characters of the results, and by the marked differences in the phenomena which are observed when regions in close local relation to each other are excited. Other facts are pointed out, bearing in the same direction; among others, the harmony and homology subsisting between the results of experiment in all the different animals.

The experiments on monkeys are first described.

Reference is made in the description to the figures of the brain, on which are delineated the position and extent of the regions, stimulation of which is followed by constant and definite results.

Generally it may be stated that the centres for the movements of the limbs are situated in the convolutions bounding the fissure of Rolando, viz., the ascending parietal convolution with its postero-parietal termination as far back as the parieto-occipital fissure, the ascending frontal, and posterior termination of the superior frontal convolution. Centres for individual movements of the limbs, hands, and feet are differentiated in these convolutions.

Further, in the ascending frontal convolution, on a level with the posterior termination of the middle frontal, are centres for certain facial muscles, *e.g.*, the zygomatic, &c. At the posterior termination of the inferior frontal convolution and corresponding part of the ascending frontal are the centres for various movements of the mouth and tongue. This is the homologue of 'Broca's convolution.' At the inferior angle of the intraparietal sulcus is the centre for the platysma.

In the superior frontal convolution, in advance of the centre for certain forward movements of the arm, as well as in the corresponding part of the middle frontal convolution, are areas, stimulation of which causes lateral (crossed) movements of the head and eyes, and dilation of the pupils.

The antero-frontal region, with the inferior frontal

and orbital convolutions, give no definite results on irritation. Extirpation of these parts causes a condition resembling dementia.

No results could be ascertained as regards the function of the central lobe or Island of Reil.

Irritation of the angular gyrus (*pli courbe*) causes certain movements of the eyeballs and pupils. Destruction of this convolution gives data for regarding it as the cerebral expansion of the optic nerve, and as such, the seat of visual perception.

The phenomena resulting from irritation of the superior temporo-sphenoidal convolution (pricking of the ear, &c.) are indications of excitation of ideas of sound. It is regarded as the cerebral termination of the auditory nerve. The sense of smell is localised in the uncinata convolution. The situation of the regions connected with sensations of taste and touch is not accurately defined, but some facts are given indicating their probable locality.

The occipital lobes do not react on stimulation. Destruction of these lobes caused no loss of sensation or voluntary motion, but an apparent abolition of the instincts of self-preservation.

The corpora striata are shown to be motor in function, and the optic thalami sensory.

Stimulation of the corpora quadrigemina causes dilatation of the pupils, opisthotonic contractions; and the utterance of peculiar cries when the *testes* alone are irritated. The nature and signification of these phenomena are regarded as still obscure, and requiring further investigation.

Some experiments have been made on the cerebellum of monkeys. They confirm the author's previous views as to the relation of this organ to co-ordination of the optic axes, and the maintenance of bodily equilibrium. The experiments are not detailed, as they will form the subject of a future paper.

New experiments on dogs essentially confirm those already published, while many new facts have been elicited. Those on jackals agree in the main with the experiments on dogs, both as to the character of the results and the localisation of the centres. New experiments on cats generally confirm, as well as further define, the results described by the author in his former paper. The facts of experiments on rabbits, guinea-pigs, and rats are essentially alike, and also confirm former statements.

In all those animals, the sensory regions are defined, and their position compared with those in the brain of the monkey.

The only result obtained by the stimulation of the cerebral hemispheres in pigeons was contraction of the pupil. The region associated with this action, situated in the postero-parietal aspect, is compared with a similar region in the mammalian brain, and regarded as the seat of visual perception.

Movements of the limbs in frogs, and of the tail and fins in fishes (as in swimming), can be excited from the cerebral hemispheres in these animals. Exact localisation of motor and sensory centres is not possible.

The optic lobes in birds, frogs, and fishes, seem related to movements of flight and progression, in addition to their relation with the eyes. Similar phenomena result from irritation of the cerebellum, but the signification of these is reserved for future inquiry.

From the data of physiological experiment, a foundation is obtained for constructing an anatomical homology of the convolutions.

Among other points in homology the fissure of Rolando is shown to be the homologue of the crucial sulcus in the brain of the carnivora.

The whole brain is considered as divided into a sensory and motor region, corresponding to their anatomical relation to the optic thalami and corpora striata, and the sensory and motor tracts.

The motor regions are regarded as essential for the execution of voluntary movements, and as the seat of a corresponding motor memory (motor ideas), the sensory regions being looked upon as the organic seat of ideas derived from sensory impressions. An explanation is attempted of the phenomena of aphasia, and the relation of the memory of words to the ideas they represent.

The theory that a certain action, excited by stimulation of a certain centre, is the result of a mental conception, is considered and disputed. From the complexity of mental phenomena, and the participation in them of both motor and sensory substrata, any system of localisation of mental faculties which does not take both factors into account, must be radically false. A scientific phrenology is regarded as possible.

The paper concludes with a short consideration of the relation of the basal ganglia to the hemispheres. The view is adopted that they constitute a subvoluntary or automatic sensori-motor mechanism.

ANATOMY AND PHYSIOLOGY.

PHYSIOLOGICAL RESEARCHES ON DIGESTION AND ABSORPTION IN THE HUMAN LARGE INTESTINE. BY V. CZERNY AND J. LATSCHENBERGER, OF FREIBURG.*

(Concluded from page 148.)

Researches on Digestion.—Coagulated egg-albumen cut into small sharply angular pieces, so that the least alteration in shape would be detected, showed no change, in spite of remaining in contact for two or three hours, at a temperature of 95° Fahr., with intestinal secretion obtained from the various openings. Even when the albumen, after being thus exposed to the intestinal mucus, was washed, and a solution containing 0.5 per cent. of chloride of sodium was poured over it, no solution or other change followed. Nor did flocculi of fibrin, placed in the same conditions, undergo the least change. Olive-oil, forcibly shaken for a long time with fresh mucus, gave no trace of emulsion. The fat floated unaltered at the surface, and the secretion retained its former transparency. Even when it was exposed to the action of mucus for some hours at a temperature of 95° Fahr., no emulsion was produced by forcible agitation.

Paste mixed with mucus, and set aside for several hours at a temperature of 95° Fahr., gave no trace of sugar. We must here remark, that not only the mucus of the exposed membrane, which might perhaps have undergone pathological changes, was used, but also that from the portion of intestine employed in the experiments, which was not affected by the pathological conditions.

In the beginning of April, a bag of network filled with coagulated egg-albumen was introduced into the rectum through the lowest fistulous opening. It

slipped from the hand of the experimenter, and could not be found; but, just before the third experiment with albumen on June 13, it appeared when the intestine was washed out. It was still full of coagulated albumen. The pieces were little changed in size and shape, but the edges were eroded, and under the microscope the albumen was found to be loaded with bacteria. It still showed the reactions of coagulated albumen; for instance, a violet colour was produced by treatment with sulphate of copper and potash. Thus, in spite of having remained two-and-a-half months in the intestine, the coagulated albumen was not essentially altered, and the changes which were present were ascribable to the action of the minute organisms which were found. There can, then, be no doubt that the large intestine does not exercise a digestive action on albumen.

Nor did albumen in solution show any change after remaining in the rectum. We must here remark that, as Subbotin has shown (*Zeitschrift für rationelle Medicin*, Reihe III., Band xxxii.), bodies are present in the filtrate of partly coagulated white of egg, which cannot be distinguished by any reaction from the so-called peptones. In fact, when submitted to qualitative analysis, these bodies showed nearly all the reactions of albumen; they gave the xanthoprotein reaction, Miller's reaction, and the reaction with sulphate of copper and potash. The remaining reactions varied with the different substances; in some cases, distinct turbidity was produced by adding a few drops of a solution of the alkaline salts of the blood. No essential differences were observed between the fresh solution of albumen and that of the fluid after removal from the intestine, except that in some specimens of the latter the reactions were more distinct and more readily produced. In order to be able to make as close a quantitative determination as possible of the above-mentioned albuminoid bodies, and for the purpose of the necessary comparison, advantage was taken of the action of absolute alcohol in producing a precipitate with most of them.

In order that the relation of these bodies to the coagulum might become readily evident, the weight of the coagulum and of the alcoholic precipitate was obtained, and the percentages of coagulum and of alcoholic precipitate were calculated. The numbers are given under the heading 'percentages of the collected precipitate' in the tables of the experiments. It was found that in fresh solution of albumen the coagulum varied between 86 and 90 per cent., and the alcoholic precipitate between 10 and 14 per cent. The coagulum and alcoholic precipitate of the fluid, after removal, varied between the same figures. In the experiments in which the solution of albumen was absorbed and the amount of alcoholic precipitate determined, slight oscillations were observed within the above mentioned limits. Thus, in the seventh experiment, on July 1, the proportion of the changed substances was less in the fluid removed than in that which had been poured in; in the latter they were 11.39 per cent., while in the removed fluids the percentage amounted to only 9.139. Again, in the fourth, fifth, and sixth experiments, in which, for reasons to be hereafter stated, there was no absorption, and which are therefore free from the objection that some of the peptones were absorbed, just the same relations were observed. In the fourth and sixth experiments, the percentages of the changed albuminoid bodies in the fluids were greater before their introduction than after their stay in the in-

* Translated from Virchow's *Archiv*, vol. lix. part 2.

testine; in the former, the percentage in the fluid introduced was 12.270, and in that removed 8.345; and in the latter it was 13.807 in the fluid poured in, and 11.690 after removal. The oscillations appeared to be dependent on coagulation; and the last named experiments, in which nothing was taken up from the intestine, show that even soluble albumen, when in solution, is not changed by the rectum or by its secretions.

Just as little does the rectum and its secretion possess an emulsive action on fat. In both the experiments the fat quickly came to the top and ran together in large drops, while the portion of the emulsion that had not been used retained its characters. Thus it was seen that the intestine had the property of again making the fat run together, which would not have been possible if the intestine and its secretion could make an emulsion of fat.*

In the experiments with starch, sugar was indeed found in the removed fluid in an experiment made on July 16; but the remainder of the paste, which had not been used, also gave slight evidence of sugar, though not a trace of sugar could be detected at the time when the fluid was poured into the intestine. Thus it is possible for sugar to be formed independently of the intestine and its secretion.

The human rectum and its secretion has no digestive action either on coagulated albumen, or soluble albumen, or on fat.

Experiments on Absorption.—To test the power of the intestine to absorb water, this fluid was poured in, in quantities of fifteen cubic centimètres, at first with an interval of half an hour; but at the second time a portion flowed out. A third and similar quantity was poured in at the end of an interval of an hour; but here again a portion escaped, and it was only when the intervals were two hours long that there was no escape. Two experiments were made on May 13 and 15. On May 13, at 10 a.m., fourteen cubic centimètres of water were poured in, at 12 noon thirteen cubic centimètres, and the same quantity at 1.45 p.m.; making in all forty cubic centimètres. At 6.30 p.m. a tube was introduced into the rectum, but not a drop appeared. In order to remove any possibility of error, twenty-eight cubic centimètres of water were poured in through the same opening, and twenty-five centimètres were at once removed *per anum*. On May 15, at 12 noon, nineteen cubic centimètres of water, at 1.45 p.m. fourteen, and at 4.45 thirteen, making in all forty-six cubic centimètres, were poured in. At 6.25, the tube was introduced into the rectum, and not a drop of water flowed out. As a test, two hundred cubic centimètres of water were poured in, of which one hundred and ninety-two escaped *per anum*. It hence results, that the portion of intestine operated on absorbed on an average from forty to fifty grammes of water in seven hours.

In order at least to estimate the error arising from the admixture of the intestinal secretion with the water used in washing out the bowel, the intestine, having been washed out on the previous day, had four portions of water, each sixty cubic centimètres, poured into it, and each portion was separately removed and its dry residue ascertained. The results in grammes for the respective portions were:—

| | | | | |
|-----------------------|--------|---------|---------|--------|
| Weight of water | 43.324 | 51.0035 | 59.3615 | 62.263 |
| Weight of dry residue | 0.1217 | 0.0952 | 0.0466 | 0.0304 |

Thus, of 240 grammes of water poured in, 215.952 grammes reappeared, with a dry residue of 0.294 gramme. The water which flowed out was turbid; and microscopic examination showed this turbidity to depend on threads aggregated in thick bundles, surrounded by masses of detritus. These threads were not of a fungoid nature; nor did they entirely agree with the constituent elementary tissues of the organism. These threads, causing the turbidity, were found in all the water that had been used for washing, both in the experiments with albumen and in those with fat and paste.

In the first three experiments on absorption with albumen, it was shown that this substance is absorbed in relatively large proportion; and in the first researches the percentages of absorbed albumen varied within comparatively narrow limits. From the solid residue, it was calculated that, in an experiment made on May 23, 70.869 per cent. was absorbed in 23½ hours; in a second, made on May 29, 61.455 per cent. in the same time; and in a third, made on June 14, 68.443 per cent. in 29½ hours. That only very small quantities remained in the intestine, was shown by the rapid decrease in the solid residue of the individual portions of water used in washing. Here, however, we must remark that, in both the first two experiments, the bag filled with decaying coagulated albumen was still in the intestine, and was washed by the water. In the third experiment, an irregularity was observed in the weight of the solid residue of the water, inasmuch as the third portion of water contained more solid residue than either of the two preceding. This irregularity depended on the circumstance that the bag of albumen already mentioned came to light on the day before the experiment, and probably some portions of the decomposing albumen had remained in the mucous folds of the bowel. In these three experiments, not a drop more of the fluid poured in appeared on introducing the tube through the anus. Thus, along with the remains of the albumen in the bowel, which was acted on by the water, so much water was removed that no more could flow out, but remained adherent to the intestinal wall. The result of the fourth, fifth, and sixth experiments was altogether different. The several columns in the tables gave negative results. On proceeding to subtract the amount of water that flowed out from that poured in, the figures were found to be negative, showing that more escaped than had been poured in, so that, in these three experiments, there was not only no absorption, but an increase of substance in the bowel. This glaring contradiction to the former two experiments was explained by the condition of the bowel. The intestine had been mechanically irritated by the preliminary measurements, and was consequently deeply reddened, its mucous secretion was much increased, while the patient at first, even when the intestine was empty, complained of frequent desire to defecate. These researches show how susceptible the bowel is of irritation, and that simple hyperæmia impedes or entirely arrests absorption. In the fourth experiment, made on June 17, 1873, ordinary solution of white of egg was used, and, on its removal from the intestine, it was found to be remarkably inspissated. While the solution of albumen that was poured in contained 5.990 per cent. of dry residue, the fluid that escaped showed 21.989 per cent. Water

* This property of breaking up emulsion, the secretion of the rectum probably owes to its alkalinity, which renders again soluble the insoluble soaps necessary for the formation of emulsion.

alone was removed from the solution. In the fifth experiment, on June 20, the conditions were altogether different. To the solution of albumen, 1·614 per cent. of chloride of sodium was added. On removal, the weight indicated the escape of more fluid than had been poured in : these quantities being respectively 61·561 and 63·314 grammes. To what this increase was due, was shown by the percentage of dry residue ; while the fluid poured in contained 7·178 per cent., that which flowed out contained 5·838 per cent. Thus the increase consisted chiefly of water. Here also, as has already been shown by many, the chloride of sodium had an irritant effect ; it increased the irritation, and water was excreted, while in the previous experiments water had been absorbed. That chloride of sodium increases irritation, was shown in the sixth experiment, made on June 25, in which only 0·489 per cent. of the chloride was added to the solution of albumen. The dry residue of the solution poured in was 5·579 per cent. ; that of the fluid which escaped, 22·163 per cent. Here again, with a small proportion of salt, water was again absorbed. The time occupied in the three last mentioned experiments was, in the fourth $7\frac{1}{2}$ hours, in the fifth $9\frac{1}{2}$ hours, and in the sixth 10 hours and 10 minutes. We must add some remarks on the peculiar relation of the chloride of sodium in the fifth and sixth experiments. While in both experiments albumen was not absorbed, and notwithstanding that the bowel showed hyperæmia and increased secretion, a large percentage of the chloride of sodium was absorbed. In the fifth experiment 70·114 per cent. disappeared, and in the sixth 71·895 per cent. That the impediment to absorption arose from the mechanical irritation caused by measuring the intestine, was shown in the next two experiments, which were carried out under the same circumstances and in similar periods of time, while the bowel had been allowed to remain perfectly at rest for five days previously. In the seventh experiment, on July 1, 16·588 per cent., calculated from the solid residue, was absorbed in $10\frac{1}{2}$ hours, although the intestine had not yet quite returned to its normal condition. In the eighth experiment, on July 7, 0·417 per cent. of chloride of sodium was added to the solution of albumen ; and here it was shown that, as in the previous experiments, the chloride impedes absorption ; only 8·190 per cent., calculated from the solid residue, was absorbed in $10\frac{1}{2}$ hours ; while 65·267 per cent. of the chloride of sodium disappeared. In the seventh and eighth experiments the fluid that had not been absorbed, and which escaped, was inspissated ; in the seventh experiment the solution poured in had 5·338 per cent. of dry residue, while the fluid that was removed contained 17·690 per cent. ; and in the eighth the amount of dry residue in the solution poured in was 5·028 per cent., in the fluid that escaped 14·842 per cent. The last experiment with albumen was made with eggs beaten to a froth and then allowed to again run together without any addition. While in all the other experiments the unabsorbed fluid removed from the bowel was very turbid, while the solutions of albumen poured in were perfectly transparent, in the experiment made on July 28, the unabsorbed fluid which escaped was nearly as transparent as that poured in ; further, the colour was just as yellow, and the consistence did not vary remarkably when compared with the former experiments. The dry residue of the albumen poured in was 11·905 per cent., of the albumen removed 12·503 per cent. ; the water used in washing, however,

was just as turbid as in the preceding experiments. Thus the fluid appears to be nearly unchanged in quality on its removal from the bowel ; it is, as it were, a fluid which does not allow mixture with the intestinal secretion. But it appears not only with the same quality, but also nearly in the same quantity. In $10\frac{1}{2}$ hours only 4·283 per cent., calculated from the solid residue, was absorbed, although the intestine was in a favourable condition for absorption, as was shown by the previous experiments.

Albumen is contained in the egg in a form unfavourable for absorption, and the sepimenta in which the albumen is enclosed appear not to be broken up by beating the egg to a froth. That the percentages derived from the dry residue indicate the albumen that has disappeared, is shown by the percentages derived from the coagulum that has disappeared, which are greater than those of the dry residue.

In the normal condition, soluble albumen (dissolved in water) is absorbed from the human rectum as such, not being changed by the intestine ; and a greater percentage is taken up, the longer it remains in the bowel. Any irritative condition of the bowel impedes absorption, or completely arrests it. Chloride of sodium also impedes absorption, but is itself taken up notwithstanding that the intestine is in a state of irritation and that absorption is suspended. In the hen's egg, albumen is contained in a form unfavourable for absorption.

In the ninth experiment, on July 11, and in the tenth, on July 13, it was shown that fat in emulsion is absorbed by the human rectum. In the ninth experiment, 15·294 per cent., calculated from dry residue, of a very concentrated emulsion of olive-oil was absorbed in $10\frac{1}{2}$ hours. In the tenth experiment, 31·342 per cent., similarly calculated, of a much more dilute emulsion, was absorbed in 25 hours. That fat was here absorbed, was shown by the percentage of fat that had disappeared as well as by the above figures. This shows, that the more concentrated the fluid is, the greater is the absorption of material in solution or in emulsion. In the ninth experiment, 3·017 grammes of a very concentrated emulsion were absorbed in $10\frac{1}{2}$ hours, while of a very dilute emulsion only 11·422 grammes were absorbed in 25 hours. The extraordinarily rapid decrease of the solid residue in the water used in washing the intestine, showed that it very completely removed the fat from the bowel.

Fat in emulsion is absorbed by the human rectum. The quantity absolutely absorbed is in proportion to the degree of concentration ; and the amount per cent. absorbed is in proportion to the time during which the fluid has been in contact with the absorbing surface.

In the experiments with paste, made on July 16 and 18, it was shown that this was absorbed. In the eleventh experiment, so much water was removed from the paste in the intestine, that not a drop of fluid appeared on introducing the anal tube. The water used in washing had an acid reaction ; the last portion only was neutral. All the portions contained starch, and showed traces of sugar. These were the only specimens of washing water which had an acid reaction, while those of all the other experiments were alkaline. This shows that any acid reaction of the contents of the intestines does not depend on the bowel itself or its secretion, but on its contents. In this experiment, 27·723 per cent., calculated from the solid residue, was absorbed in $10\frac{1}{2}$ hours. In the twelfth experiment, on July 18,

which was made with paste, not a drop of fluid appeared on introducing the tube into the anus. The portions of water used for washing had a neutral reaction; they showed no trace of starch or of sugar, but, on testing for sugar with potash and sulphate of copper, they gave a violet colour, indicating albumen. Thus all the starch which was poured in was taken up by the intestine, and not a trace of it remained—no lactic acid or sugar. The solid residue of the water used in washing the bowel consisted only of the detritus of the intestine.

Starch in the hydrated form is absorbed by the intestine; whether as such, or after being changed into sugar, is not decided by these experiments.

The greatest quantity of albumen absorbed in 29 hours was about $1\frac{1}{2}$ grammes. As the large intestine is on an average about four times as long as the portion which served for experiment, this indicates an absorbent power, in the whole large intestine, of 6 grammes of soluble albumen from a solution containing $4\frac{1}{2}$ per cent. This quantity is far from being sufficient for nutrition, as about 120 grammes are necessary for a healthy man (Voit and Bauer). The quantity of albumen absorbed is evidently increased when more concentrated solutions are used.

General Result.—The human rectum absorbs soluble albumen unchanged, as such; it also takes up emulsion of fat; starch also is absorbed, but it remains undecided whether it be absorbed as starch, or whether it must first be changed into sugar. Chloride of sodium impedes or completely arrests absorption.*

[To the paper are appended tables, showing the results in each of the experiments.]

MEDICINE.

LATOUR AND OLLIVIER ON MORBID SWEATING OF THE FEET AND ITS TREATMENT.—Dr. Debrousse Latour has lately published a thesis on local sweatings, in which the unpublished observations of M. Ollivier, of the Paris Faculty of Medicine, are incorporated with those of the author.

The forms of local sweating which offer the greatest number of interesting points are, according to Hebra, those which affect the armpits, the genital organs, the palm of the hand, and the sole of the foot. For the present, M. Debrousse Latour confines his remarks to the last-mentioned affection, which elevation of the temperature for the time being raises into a really insupportable condition of disordered function. The causes of this morbid perspiration are little known; it is not an attribute of the lymphatic temperament, nor always of a want of cleanliness; it is not contagious, nor does anything prove it to be

* This property is probably possessed by crystallised substances in general. Our patient's bowel, after a solution of sulphate of magnesia had been poured in, showed violent reaction for some days; it was strongly reddened, the mucous secretion was much increased, and shreds of mucus, containing abundant epithelial cells, escaped *per anum*. Even the peptones act as irritants, as has been shown by Bauer and Voit. This is the reason why so many clinical experiments fail, as only solution of uncoagulated albumen, without any addition, emulsions of fat, and starch, do not act as irritants and therefore can be borne for some time. Added substances, which irritate the intestinal mucous membrane, impede absorption, and later on arrest it.

hereditary. Its symptoms are well known, as well as the disagreeable accidents to which it gives rise.

The question arises whether it is prudent to accede to the wish of the patients who desire to be relieved from the annoyance of this affection. Without following the author through all his arguments, it will suffice to say that he agrees with almost the whole of the French medical profession in the belief that it is dangerous to suppress habitual sweating of the feet. 'Perhaps, however,' remarks Debrousse Latour, 'we must here draw a distinction between patients having a good constitution and those predisposed to pulmonary phthisis or phlegmasiæ of the respiratory organs.' In support of this judicious reservation, the writer cites the following fact, observed by M. Ollivier in the case of a medical student whom he treated.

M. X., aged twenty-one, had been troubled during two years with partial sweatings of the feet, of an extremely disagreeable character. In other respects he was in good health, and there was nothing abnormal in the action of the organic functions; the appetite was good, and thirst moderate. The local sweating was so profuse as to oblige the sufferer to change his socks several times in the course of the day, and it exhaled a fetid odour, although it was clearly of a watery nature. The skin of the feet was whitish, and, as it were, macerated. M. Ollivier, nevertheless, found no indication against treatment for partial hyperidrosis. He prescribed foot-baths with Barèges water, a preparation of iron, and cold douches. In two months the malady had disappeared, and the cure afterwards continued without any change in the health of the patient. The hygienic treatment of this morbid state in delicate patients consists in avoiding sudden cooling of the feet. The patient should wear stout shoes or boots and woollen stockings, which should be changed frequently. If, in consequence of chill, sudden suppression of perspiration be followed by any unpleasant consequences, the sudorific hypersecretion should be brought on again by the use of very hot foot-baths, and afterwards by wearing woollen socks covered with oiled silk, or even stockings sprinkled with chlorhydrate of ammonia mixed with quicklime, in the proportion of two parts of the latter to one of the former. As a means of diminishing the disagreeableness of excessive and fetid perspiration, the following disinfectants may be used with advantage; the solution of permanganate of potash (0.05 centigrammes of permanganate of potash to 250 grammes of water), or the solution of tincture of coal-tar (1 gramme tincture of coal-tar to 250 grammes of water). If the epidermis become softened by maceration, if it fall off, leaving the *rete Malpighii* exposed, and thus render walking difficult and painful, Hebra unhesitatingly recommends that the soles of the feet and the toes should be coated with a mixture of equal proportions of compound diachylon plaster and linseed oil, which should be melted before it is used; the excoriated portions should afterwards be covered with linen. So much as regards palliative treatment; but if the good constitution of the patient give warrant for more active measures, then lighter boots and thread stockings should be ordered, together with lycopodium, charcoal, and tannin powders.

M. Gaffard, of Aurillac, recommends allowing some drops of the following liquid to penetrate between the toes.

| | |
|-----------------------------|-------------|
| Red oxide of lead | 1 gramme. |
| Subacetate of liquor plumbi | 29 grammes. |

We have already seen how M. Ollivier succeeded

in effectively combating sweating of the feet with Barèges water and cold douches. Lotions with aromatic vinegar will also be found useful. Another means consists in spreading frequently in thin layers on the secreting parts clay softened in water and passed through a sieve. As to medicines given internally, and praised as specifics against general sweatings, such as the *Polyporus officinalis*, and the acetate of lead, MM. Ollivier and Debrousse Latour have arrived at the conviction that they are powerless against perspiration of the feet and other local sweatings.

CLINICAL MEDICINE.

CHARCOT ON THE DIAGNOSIS OF HYSTERO-EPILEPSY FROM TRUE EPILEPSY.

M. Charcot, in a recent clinical lecture at the Salpêtrière, called attention to the traits which distinguish hystero-epilepsy from true epilepsy. In hystero-epilepsy, M. Charcot says, the attack is always announced previously by premonitory symptoms of rather long duration. In every kind of hysteria that can be called ovarian, these premonitory symptoms consist in an aura starting from the ovarian region, and reaching successively the epigastrium, the neck, and finally the head. These premonitory phenomena, so curious, and of an incontestable diagnostic value, are wanting in epilepsy; in epilepsy, the premonitory symptoms are sensations in altogether a different part, which ordinarily precede the attack only by a few seconds.

The cry of the hystero-epileptic at the moment of the fall is generally prolonged and modulated; it can hardly be confounded with the short cry of the epileptic. When the patient has fallen, the symptoms in the two affections are much alike; the head and eyes are turned in the same way, the limbs are taken with tonic convulsions; the whole body becomes rigid, the face congested, and a bloody froth flows from the mouth. But the differences soon reappear; at the moment when the epileptic is seized with a snoring which recalls the apoplectic stertor, the hystero-epileptic seems on the contrary to wake up, sometimes to return to the former condition, sometimes to offer a succession of symptoms making, in some way, a new period, which might be called the period of contortions. These contortions, sometimes very extraordinary and alarming, are very variable, and it can be said that in every patient, in spite of some traits in common, they are different. During this time, the hystero-epileptic seems to be affected by delirium, sometimes noisy, and which seems in a great part to give the contortions and attitudes and gestures an intentional character. To the contortions succeed, in the hystero-epileptics, delirium relatively quiet, one of the characteristics of which are hallucinations of the sight and hearing. They hear bells and voices, &c., they see every kind of animal, butterflies fluttering along the ceiling, lizards climbing

the walls, vultures coming to peck their faces; they try by gestures to escape from these imaginary beings; at other times they imagine themselves walking over serpents, and they give jumps to avoid them, &c.

This delirium, which at this point resembles in a certain degree delirium tremens, is quite different from epileptic delirium, which consists mostly in a maniacal excitement, accompanied sometimes with extreme violence, and of a gloomy character, which renders the patients very dangerous.

If it be a woman who is threatened by an attack, the nature of which is doubtful, compression on the ovary will contribute to clear up the diagnosis; if there be no effect, then one has to do with an epileptic; in the hystero-epileptic, though the ovary may be but slightly affected, it will produce, if not always a complete arrest of the attack, at least a modification more or less marked in the symptoms.

Sometimes, and this also in hystero-epilepsy as well as in epilepsy, the attacks are connected in a series, and produce in the one case a state of hystero-epileptic disease, in the other a state of epileptic disease. In these cases thermometry gives important assistance; in the epileptic in a state of disease the temperature rapidly attains a great height, 40°, 41°, and even 42° (Cent.), and death often closes the morbid scene; in the hystero-epileptic, in spite of the almost incessant repetition of the attacks of an extreme intensity, the thermometer marks 37.5°, 38°, and a few tenths. After 50, 100, and 200 attacks of hystero-epilepsy, the temperature is definitely the same as it was at the end of the first attack.

Besides the convulsive accidents there are, adds M. Charcot, other characteristics which facilitate the diagnosis. Epileptics are irascible, subject to impulses which make them dangerous; hystero-epileptics are capricious, fantastic, but are on the whole hardly dangerous. Vertigo, which is so frequent in epilepsy in the interval of the attacks, has not its representative in hystero-epilepsy.

The mental condition, which has already been treated by many authors, is seen in the end to be not different in the two diseases. The hystero-epileptics preserves those intellectual faculties which they had originally. One of the patients shown was in this respect the same as she was thirty years ago in spite of the persistence of the disease. The epileptic, on the contrary, if the disease be intense, loses his intelligence every day, and at the end of a time more or less short, he falls into a kind of stupor, which generally ends in true dementia. These principal distinctive marks, said M. Charcot, useful already to establish a nosographic demarcation, will suffice, in general, to separate clinically two affections of which the prognosis markedly differs.

CLINICAL SURGERY.

COLES, COLEMAN, AND OTHERS, ON THE MECHANICAL TREATMENT OF CLEFT PALATE.

A very interesting discussion is reported in the *Transactions of the Odontological Society of Great Britain*, vol. vi. no. 2, on the treatment of cleft palate by the use of various modifications of Kingsley's obturators. It is important to notice that, in the experience of the speakers, the mechanical is more successful than the surgical treatment of cleft palate.

Mr. Oakley Coles felt that the dentists of this country were under great obligations to Dr. Norman Kingsley for the amount of labour he had bestowed in bringing these moulds to so great a perfection. The form of his instruments was in some respects similar to an instrument invented by Stearn, an English surgeon, many years back; but to Dr. Kingsley was due the merit of constructing them in rubber. He (Mr. Coles) had had the opportunity of seeing some of Dr. Kingsley's earlier moulds; they were perfect pieces of sculpture, such as could only be produced by a master-hand. With reference to the precise form of instrument Mr. Turner had exhibited, he could not consider it of a novel character, as it was very similar to that which Mr. Ramsay had constructed and described—that, however, was a minor matter. With regard to the question of cheapness—at least for hospital purposes—it was quite possible to meet most cases by the ready-made plan. The cases of cleft palate after a time repeated themselves, so that it was quite possible out of a large stock to fit the majority of them; and having such a stock, he would be glad to place his moulds at the service of any member who might require a case in hospital practice. He felt they were not only indebted to Dr. Kingsley but also to Mr. Turner, who had exhibited to them a series of moulds the nearest to perfection he had ever seen.

Mr. Coleman would ask Mr. Coles, as his experience in the employment of those instruments had probably been longer than that of any other member present, whether there was any tendency to enlargement of the cleft after they had been worn for some time. It appeared to him the chance of this might be greater, when the instrument had not been made specially for the case. If there were any pressure upon the margins of the cleft by that portion of the instrument which might be termed the central portion of the stud, it appeared to him almost certain such a result would follow. When a very elastic substance like sponge was used, the enlargement was very considerable; and there was in the museum of St. Bartholomew's a preparation showing this in the case of a woman, who, having commenced with a small piece of sponge, ultimately employed a piece which might have done for the ordinary domestic purposes of washing. The soft rubber might to a small extent act like the sponge.

Mr. Coles, in reference to the remarks of Mr. Coleman, would observe that he did not think it so desirable as Mr. Turner appeared to, that the sides of the cleft should be accurately fitted; when it did fit closely you certainly did get a certain amount of absorption or irritation of the margins; whereas if the connecting portion of the two flanges were made smaller, you positively got in time a narrowing of the cleft. In a case where at ten years of age a surgical operation would have been hardly possible, at fifteen, after wearing it, it had become quite practicable to do so.

Mr. C. S. Tomes said that the observations of Mr. Coles reminded him of an important question connected with this subject not touched upon by Mr. Turner. The operation of staphyloraphy was at one time very largely performed at the Boston General Hospital, at the hands of Dr. Bigelow and others, but especially the former, and the hospital had so great a reputation, that cases were sent to it from all parts of America. There were some peculiarities in the mode of operation they adopted: thus the patient was laid on one side, with the head rather below the rest of the body, and the operation was performed under the

influence of an anæsthetic. By careful attention to a variety of details they attained the greatest surgical success possible; nevertheless, so good were the results of Kingsley's obturators, that the operation had been quite discontinued, not one having been performed during the last two years; and not merely this, but some of the cases which had been operated on were slit up again to receive Kingsley's obturators, because such infinitely better results as regarded speech and deglutition were thereby attained. With regard to the observations of Mr. Coleman and Mr. Coles, he did not think there was a likelihood of those evil results occurring under Dr. Kingsley's hands; for when that gentleman was fitting some of his instruments to plaster models to illustrate their adaptability to different cases, he observed that he invariably selected one smaller than that he (Mr. Tomes) would have considered suitable to the case. The impression left on his mind was rather stronger than Mr. Turner had put it in reference to the question of adaptability; he rather inferred from what Dr. Kingsley told him, that he would now prefer adapting an instrument made from an old model to constructing it from a new one, and he showed him a large number of them strung together ready for application to any but a very extraordinary case. He had the opportunity of seeing one of them put into the mouth of a patient for the first time. It produced very little irritation or discomfort, and improvement in the voice was at once perceptible.

Mr. West would like to ask Mr. Turner if he could give any idea of the durability of those obturators; they appeared to him so thin and flexible as to be likely soon to wear away in the act of deglutition.

Mr. Edwin Sercombe would venture to make one remark in respect to the comments of Mr. Coleman. He did not see how it would be possible for enlargement to take place in the fissure if the obturator fitted it accurately. If it impinged upon it, it no doubt would. The oldest case that he had had to deal with showed no such enlargement, although the instrument had been worn, fitted against the margins of the cleft, some twenty years. With a material like sponge, enlargement would rapidly take place. They all well knew how with cotton-wool they could separate the teeth; but with a material which did not sensibly expand, like hard vulcanite, he did not think there could be any fear if it fitted properly. That there should be no pressure upon the margins of the cleft he had laid down as most important in a paper on the subject read before the Society during the first year of its existence. He would like to ask Mr. Tomes what success had attended those cases in which Dr. Bigelow had slit up the velum united by surgical means. The results of the closure by surgical means had, according to his observations, been anything but successful in attaining the most important object in view; viz. a more distinct enunciation. This he attributed partly to the lessening of the oral cavity resulting from contraction of the cicatrices.

Mr. Tomes, in reply to the president, said that in one case he knew that a favourable result was obtained, but the velum was not slit up throughout its whole length. Both Dr. Bigelow and Dr. Kingsley spoke about the improvement effected in it. In another case it was slit up throughout its whole length, but with what result he did not learn.

MATERIA MEDICA AND THERAPEUTICS.

HASSE ON TRANSFUSION OF LAMB'S BLOOD INTO MAN.—Dr. Hasse, of Nordhausen, relates in the first part of a valuable and very interesting monograph, sixteen cases of mediate transfusion of venous defibrinated human blood, performed by himself during the years 1869-72. In the second part, he describes fifteen cases where he performed immediate transfusion from the carotid artery of the lamb to the vein of the patient during 1872 and 1873. The third part gives an account of his method of performing both mediate and immediate transfusion.

The first series of Dr. Hasse's cases show four cases with good results (phthisis, two cases of chlorosis, and one of marasmus of a child); ten cases with temporary improvement, but with death following at last (five cases of phthisis, one of pyæmia, one of amyloid degeneration, one of marasmus after dysentery, one of marasmus after enteritis, one after scarlet fever); and two cases where little or no improvement followed, but which did not die (anæmia following abortion and uterine disease). Cases of immediate death after the operation did not occur.

The second series contains fifteen cases where lamb's blood was injected by the immediate method. There are eleven cases of good, even surprising results (six cases of phthisis, one of anæmia after enteritis in a child, one of anæmia after placenta prævia, two of anæmia after puerperal disease, one of chlorosis); three cases where the improvement was only slow and less perceptible or temporary (one case of caries of the spine, one case of anæmia resulting from pneumonia and dysentery, and one of cancer of the stomach); and one case of tabes dorsalis, where death occurred four hours after the operation, with a rise of the temperature to 109° Fahr.

Respecting this one case of unhappy result, Dr. Hasse believes that in consequence of the severe disease of the nervous centres, transfusion would better have been avoided, but that the lamb's blood itself was not the cause of death. The success was most brilliant in those eleven cases of almost otherwise incurable diseases where the operation really saved the lives of these patients; and it seems that we have now in transfusion a very valuable means of treating of consumption, even in desperate stages. The general state of these patients soon improved, as well as the local symptoms.

Dr. Hasse thinks that the use of lamb's blood is preferable to that of defibrinated human blood, not only because danger to the blood-donor is avoided, but also because the effect of lamb's blood on the disease is more powerful and permanent. He lets pass over as much blood as the patient can bear, viz. till certain symptoms appear, which regularly follow this kind of transfusion.

During the first twenty to thirty seconds the patient has a warm feeling running up the arm. The veins begin to swell, the skin of the arms and the chest become red, and some perspiration may be seen on the face. Then dyspnœa sets in, and is followed by a feeling of fulness of the abdomen. Sometimes, sickness and an irresistible tendency to go to stool are observed. At last headache, giddiness, and fainting take place. All the patients complained of pain in the back, which lasted sometimes several hours, but sometimes disappeared very soon. In a time vary-

ing from ten minutes to an hour after the operation, shivering sets in, with a rise of temperature for several degrees. This is generally followed by perspiration and a sound sleep, from which the patient awakes in greater strength. In several cases the urine on the following morning contained albumen and hæmatin, which disappeared the same day; but he never found any blood-corpuscles. Some days later, in most cases, there was an eruption of urticaria.

The mode of operating employed by Dr. Hasse is simply as follows. He exposes the carotid artery of a lamb for four or five centimètres (about 1½ to 2 inches), puts a ligature round the vessel at the peripheral end, and inserts into the central part of it a glass tube filled with a solution of bicarbonate of soda, and fitted with an India-rubber tube from five to six centimètres long. Then he inserts a glass tube, also filled with the solution, into the vein of the patient. He draws off the India-rubber from the patient's tube, and, having seen that the stream of the blood passes well from the lamb, connects the two glass tubes with the India-rubber fitted to the lamb's cannula. Now transfusion is going on, and the proceeding is continued until the above-named symptoms show themselves, and till the oppression and dyspnœa indicate that the operation should be interrupted. He then applies two ligatures to the vein and cuts it, dressing the wound in an ordinary surgical way. He has never seen phlebitis after this mode of operating.

[From a private letter of Dr. Hasse, we know that he has enlarged the number of cases where he performed transfusion from a lamb since, and we can only congratulate him for having with such energy and success promoted this highly interesting object, in spite of the many difficulties of practice in a provincial town.—*Rep.*]

P. SCHLIEP, M.D., Berlin.

BUCQUOY ON THE CURE OF TUBERCULOUS ULCERATION OF THE TONGUE.—M. Bucquoy, at a meeting of the Société Médicale des Hôpitaux (*Bulletin de Thérapeutique*, January 15), reported the cure of a case of ulceration of the tongue, which, when presented to the society three months previously, had been recognised by all as of a tuberculous nature. The ulceration of the tongue was now healed, but the pulmonary mischief had considerably increased. The treatment had consisted of the application to the ulcer of very dilute tincture of iodine; the general treatment had been tonic and sedative.

BROUARDEL ON NUMERATION OF THE CORPUSCLES IN TRANSFUSION OF BLOOD.—M. Brouardel (*Bulletin de Thérapeutique*, January 15) gives an interesting report on a case of transfusion of blood in an individual dying of prostration from incoercible vomiting after swallowing sulphuric acid. 150 grammes of blood not defibrinated, taken from his house-surgeon, M. Landouzy, were injected into the vein of the arm. The immediate consequences were favourable, but in twenty-six hours a relapse occurred, and the patient died with hepatisation of the lower lobes of the lung. The necropsy showed ulceration of the pylorus. This observation showed this important point, that the application of M. Malassez's new method of numeration of the blood-corpuscles (*LONDON MEDICAL RECORD*, January 8, 1873) has allowed it to be ascertained that a rapid destruction of the elements of the blood occurs when the individual cannot repair the incessant losses of the economy; while, in an individual in good health,

repair is rapidly effected. Thus the patient had 3,200,000 red corpuscles in the cubic millimetre of blood; after the injection of 150 grammes of blood the figure was raised to 3,200,000; but thirty hours afterwards it was again at the previous figure of 3,200,000; while in M. Landouzy, who had lost 300 grammes of blood, the number of blood-corpuscles before the bleeding was 4,300,000, immediately after it 4,000,000, and twelve hours afterwards 4,100,000. M. Dujardin-Beaumetz related a case of obstinate anæmia, in which transfusion produced a temporary benefit, as in the above case, and was twice repeated when that effect had passed off; the amelioration after the third transfusion was, however, of very brief duration, and the patient died on the following day. The results of the enumeration of the corpuscles mentioned above gives a key to the transitory effects of transfusion in these cases.

LAUTH ON THE TREATMENT OF ASPHYXIA OF INFANTS BY THE INDUCED CURRENT.—Dr. Lauth (*Gazette Médicale de Strasbourg*, no. 19, Dec. 1873, p. 238) relates three cases of asphyxia of infants in which ordinary methods of treatment failed, while the employment of electricity led to complete success in one case and temporary success in the two others. He recalls the rules for its employment. He uses one of Gräfe's apparatus, and advises the practitioner to pass the dry reophores of the apparatus along the vertebral column and over the brachial plexus at its point of divergence, between the scapuli, along the external border of the sterno-cleido-mastoid muscle. He recommends also excitation of the mastoid-nerve. Each of these applications should be made for two or three minutes, and the intervals should be used for applying insufflation. He refers to Boer of Vienna (*Untersuchungen und Versuche geburtshilflichen Inhalts*, vol. ii. p. 15) as having first applied this method of treatment for the insufflation of newborn infants in 1791. See also Oppenheim's *Zeitschrift*, vol. xxv. p. 109 (1846); Scholz (1851); Gunzberg's *Zeitschrift*, vol. ii. p. 26-35, and Bæhr (1861) in *Monatsschrift für Geburtskunde*, vol. xviii. In France, Duchenne (de Boulogne), Onimus, and Le Gros, have advised this mode of treatment.

LUTON ON THE TREATMENT OF ALCOHOLISM BY NUX VOMICA.—Dr. Luton (*Mouvement Médical*, December, 1873), describes excellent effects from the use of nux vomica in chronic alcoholism, where the evil has not passed into the absolutely degenerative stage of tissue-change. In the tremors, cerebral disorder, and gastro-intestinal and thoracic disorders of alcoholism, he resorts with confidence to the use of extract or tincture of nux vomica in ordinary doses.

BESNIER ON THE COMBINATION OF OPIUM WITH CHLORAL-HYDRATE IN THE TREATMENT OF THREATENED ABORTION.—In the *Bulletin de Thérapeutique*, vol. lxxiv. p. 284, is summarised a case by M. Martineau in which uterine contractions occurring in a pregnant woman (seven months), treated unsuccessfully by opium, were immediately arrested by administration of chloral in the dose of 1 gramme night and morning. M. Besnier (*Union Médicale, Gazette des Hôpitaux*, no. 122), relates in connexion with this case, that of a primipara pregnant six months, and urgently threatened with abortion. Opium in high doses and under all forms not having produced any good effect, M. Besnier had recourse to chloral-hydrate in enema (2 grammes).

The effect was rapid and very satisfactory, and each time the pains reappeared they were set at rest by the repetition of the enema; but, as they did not finally disappear, M. Besnier, by advice of M. Tarnier, returned to the opiate treatment, which had to be continued for two days; it had no bad effect whatever, and the patient was saved from her threatened death. Investigating the mode of action of the chloral in these circumstances, M. Besnier concludes (with MM. Bourdon and Martineau), that chloral exercises different effects on the uterus, according as it is administered during accouchement or after a threatening of abortion. In the first case it augments, and in the second it diminishes, and, even suppresses the contractions. According to Besnier, the myosthenic or amyosthenic effects produced must severally be referred to the different conditions of the uterus at the time of administration of the chloral-hydrate. In accouchement there is to be considered the excitation of the cervix uteri by the head of the infant, which keeps up its contractions; these are even augmented as the consequence of the rest given to the womb by the cessation of pain, due to the administration of chloral. In threatened abortion, excitation of the cervix is absent: pain plays the chief part. Thus chloral suppresses the principal cause of the contractions. The whole importance of the drug lies in the analgesia which it produces. The action of the opium must also be taken into account in the case above cited. M. Besnier concludes that chloral is an excellent auxiliary to opium, when the latter proves inefficacious.

PELTIER ON THE USE OF TRIMETHYLAMINE IN THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM.—Dr. G. Peltier (*Progrès Médical*, nos. 12, 17, 19, 20, 22, and 25, 1873, and no. 2, 1874) discusses the whole of the recent observations on this subject (forty-eight in all), and analyses them. Taking them all together, it appears that of forty-eight cases treated by trimethylamine, twenty-two cases were cured in less than eight days, eighty-one in eight to fifteen days, seven in fifteen to thirty days, and eight have not appeared to be much, or at all, influenced by the treatment. He believes that no other therapeutic treatment can claim such results, and he entertains the conviction that trimethylamine will render henceforth still more marked advantages, when pure trimethylamine only shall be employed, or when only hydrochlorate of trimethylamine is used, a substance of which the dose is much more easily defined. His final conclusions are these. 1. From the point of view of its chemical action, it is preferable to employ in medicine the hydrochlorate of trimethylamine. 2. From the point of view of its physiological action, trimethylamine is a slight excitant of the skin, a caustic of mucous membrane, a sedative of the nervous system, hyposthenic of the arterial system; it diminishes the amount of urea in the urine. 3. From the point of view of therapeutic action, trimethylamine has hardly been employed in anything else than in articular rheumatism; it calms the nerves, relieves the congestion of the articulations, and diminishes the fever. On the whole, it appears to be the drug which, up to the present time, has given the best results.

FORMULARY.

SMITH ON A REMEDY FOR TOOTH-ACHE.—Dr. Q. C. Smith, of Cloverdale, writes.

'Having spent a number of years of my professional life in the country, where no dentist was

near, and therefore being often called to prescribe for tooth-ache, I tried many combinations of drugs, and many published formulas, with more or less satisfaction to myself and patients. But several years since I hit upon the following combination, which I have found better than any I have ever used, and it will give relief in almost all cases where such a remedy is applicable. Take of carbolic acid, saturated solution; hydrate of chloral, saturated solution; camphorated tincture of opium; fluid extract of aconite, of each an ounce; oil of peppermint, half an ounce. Mix. Apply by saturating a pledget of cotton (or preferably a small piece of sponge) and pack closely into the cavity of the decayed tooth.

PUBLIC HEALTH.

VÆLCKER ON MILK ADULTERATION.—Dr. Vælccker (*Pharmaceutical Journal*, March 14) writes on this subject as follows. Milk is a whitish liquid of an agreeable, sweetish taste, and faint but pleasant odour, depending in some measure upon the nature of the food upon which the cows are fed. It is essentially an emulsion of fatty particles in a solution of caseine and sugar of milk. The fatty matter is not contained in milk in a free state, but enclosed in little cells of caseine, which occurs also in milk in a state of solution, and is precipitated spontaneously as curd when milk gets sour. Viewed under the microscope, milk appears as a transparent fluid, full of small, round, or oval, and more or less angular bodies—the so-called milk-globules. When milk is left undisturbed for some time, these milk-globules rise to the surface, forming the cream of milk. Skimmed milk has a bluer colour, and is more transparent than new milk containing its full share of milk-globules or cream or butter-globules. The amount and quality of the food given to cows exercises a most remarkable influence on the quality and composition of milk. Besides this, the season of the year, distance from the time of calving, the breed and size of the cows, and several other circumstances which will suggest themselves to practical men, have a greater or less influence on the yield of milk and its quality. When residing at Cirencester College, with a view of ascertaining what may be the variations in the course of a year in the quality of milk on one and the same farm, I took samples of the milkings of all our milch cows, and analysed the morning's and evening's milk of the first or second day of each month. The milch cows were out at grass from May till the end of October, and, as the herbage then became so scarce as not to afford sufficient nourishment, they were fed in the evening at the stall on roots and hay, &c. It will be seen by the appended analyses that both the morning's and evening's milk in September were extremely poor. The poverty of this milk was therefore evidently due to an insufficient supply of food. The milk produced on two other farms in the neighbourhood during the same month, on being analysed, was found to contain $12\frac{1}{2}$ per cent. of solid matter, including $3\frac{1}{2}$ per cent. of fat (pure butter), and the same per centage of curd; showing that on both farms where the cows were supplied with a sufficient amount of nutritious food, the milk was of good quality, whereas on the College farm the scanty supply of poor grass had the effect of producing

poor milk, containing 90 per cent. of water, and only 2 per cent. of fat. The influence of food on the quality of milk was also clearly visible in the cows of the College farm. On account of the insufficiency of the grass, the cows were driven into the stall and there supplied with roots, hay, and meal. The milk became better at once, for the morning's yield then contained $12\frac{1}{2}$ per cent. of solid matter, and in this nearly 4 per cent. of butter. The concentrated food which the cows received in the evening was evidently made into good rich milk during the night. At this time the cows were put on grass early in the morning, and allowed to pick up what they could. This was not much, as their anxiety in the evening to be let into their stalls clearly showed. The influence of a stinted supply of grass was noticed at once in the poverty of the evening's milk. The percentage of solid matter fell to $9\frac{3}{8}$ instead of $12\frac{1}{2}$ per cent., and the butter to 3 instead of 4 per cent. I would direct especial attention to the fact that these analyses were not made with milk of a single cow, but that of the whole herd, and as the milch cows were kept entirely for the use of the College, there can be no question as to the genuineness of the supply.

COMPOSITION OF MORNING AND EVENING'S MILK PRODUCED ON THE ROYAL AGRICULTURAL COLLEGE FARM, CIRENCESTER.

I have alluded specially to these variations in the quality of milk as influenced by food, because some statements have lately appeared in a little work on milk-analysis, written for the special benefit and instruction of food-analysts, 'a new class of men,' which has lately been 'constituted to watch over the food of the country.' I leave it to you to form your own opinions from the following extracts taken from this treatise. According to the author, country milk of average quality contains in 100 parts by weight.

| | |
|----------------------|-------|
| Water | 87.55 |
| Fat | 3.08 |
| Caseine | 4.04 |
| Milk-sugar | 4.62 |
| Ash | .71 |

100.00

Town-fed milk, according to his analysis, contains in 100 parts by weight.

| | | | | | | | | | | | |
|------------|---|---|---|---|---|---|---|---|---|----|----|
| Water | . | . | . | . | . | . | . | . | . | 85 | 94 |
| Fat | . | . | . | . | . | . | . | . | . | 4 | 00 |
| Caseine | . | . | . | . | . | . | . | . | . | 5 | 02 |
| Milk-sugar | . | . | . | . | . | . | . | . | . | 4 | 31 |
| Ash | . | . | . | . | . | . | . | . | . | | 73 |

100'00

It will be seen that the latter milk shows a difference of one-third more of fat and one-quarter more than the amount of caseine contained in the former, and a corresponding smaller amount of water. These differences are sufficiently striking to show, at all events, that milk has not a uniform composition. Nevertheless, our author says, 'Milk exhibits great constancy of composition; the effect of variations in the diet of the cow showing itself in the amount of the secretion, rather than in its quality;' and again, 'As will be readily comprehended, this constancy of composition is a cardinal fact in milk-analysis. If milk were variable in strength, as urine is, chemical analysis would fail to detect the watering of milk. That milk is a secretion of constant, or only slightly varying, composition, lies at the very root of the subject of this treatise.' In the face of the evident contradictions between the facts given and the opinions expressed by this same author, I think I need not detain you by criticising other portions of the treatise, but leave you to draw your own conclusions as to the value of the frequent use he makes of what he calls 'normal milk.' One might as well talk of a 'normal potato,' or a 'normal cabbage,' or a 'normal pig.' On passing along on the top of an omnibus a short time ago, I was somewhat amused at seeing an advertisement of a wine-merchant of his 'standard sherry;' and I am surprised that standard or 'normal milk' is not advertised, as it might be with quite as much reason as 'standard sherry.' A great deal has been said and written about milk-adulteration. Sheep's brains, starch, chalk, and pipe-clay are said—on what authority nobody has ever decided—to have been found in milk; but the basis for these statements exists only in the imagination of credulous or half-informed scientific men, who, in want of more profitable occupation, take to book-writing. It would be difficult to understand where all the sheep's brains should come from; nor is it probable that chalk or other insoluble substances not easily kept in suspension, should be employed in adulterating milk. I have never found myself, nor have I ever met any chemist who has found, any of the clumsy adulterations often referred to in popular treatises on food. Milk adulteration resolves itself into one of two things—either the addition of water, or the abstraction of cream; and the question which naturally arises is: Can we detect to a nicety how much water has been added to, or how much cream has been abstracted from, a given sample? I have, perhaps, had as much experience in the examination of milk as anybody in England, and I fearlessly say that, owing to the natural variations in milk, it is utterly impossible in all cases to ascertain whether a small quantity of cream has been removed from milk, or an inconsiderable proportion of water has been added to it; and I further maintain that it is a reckless proceeding on the part of any analyst to assert that milk has been adulterated with exactly 8 per cent. of water, or with 13.75 per cent. of skimmed milk, as in one case, or with 16.25 per cent. as in another. Such assertions can only be made by young and inexperienced men, for whose special instruction such milk treatises as I have above referred to are compiled. No wonder that men who entertain

such inconsistent views of 'normal milk' should be led to give reports in which they positively assert that they have found 16.25 per cent. of skimmed milk, because the amount of fat did not come up to their standard by a few decimals. I may state, in passing, that in a recent case the milkman, who was accused of selling milk adulterated with 16.25 per cent. of skimmed milk, was fined in the 'mitigated penalty of 5*l*,' with the alternative of ten days in gaol. In the course of the trial testimony was given by a worthy town councillor, who had carried on business as a temperance hotel-keeper, that the accused had been known to him for the last twenty years, and had during the whole of that time supplied him with milk. He further expressed his opinion that no better milk was to be obtained than that of the accused, against whom he had never known any complaint. A well-known chemist, moreover, was called for the defence, and, on the strength of the analysis, he pronounced the milk to be of the quality of good ordinary country milk, quoting, in support of his opinion, no less an authority than the late Professor Johnstone, but apparently to no purpose, because the amount of fat contained in the milk differed in a trifling extent from what the food-analyst conceived to be the amount contained in 'normal milk.' A medical man, called in support of the prosecution, gravely stated that milk containing 16.25 per cent. of skimmed milk would be prejudicial to the health of the very young, although its effects would be hardly appreciable on an adult. Instances of this kind would be very ludicrous but for the serious consequences involved, and the injustice which, no doubt, is frequently dealt to honest dealers. Let it, however, be clearly understood that I have no intention of throwing cold water upon the system of chemically examining milk. All I desire to show by these observations is, that milk-analyses should be conducted by men upon whose practical experience and acquaintance with the subject reliance can be placed. Chemical analysis can do much in the way of revealing adulteration of food, and there is no difficulty in discovering whether milk has been skimmed or watered to any great extent. As the result of my own experience, I may state that milk may be considered rich when it contains from 12 to 12½ per cent. of solid matters, 3 or 3½ of which are pure butter. If it contain more than 12½ per cent. of solid matter and have 4 per cent. or more of fat, it is of extra rich quality. Such milk usually throws up from 11 to 12 per cent. of cream (by bulk) after standing for twelve hours at 62 degrees Fahr., and it has a specific gravity varying from 1.028 to 1.030. Good milk of fair average quality, as has been stated already, contains from 10½ to 11 per cent. of dry matter, including about 2½ per cent. of pure fat. It yields 9 to 10 per cent. of cream, and has a specific gravity of about 1.030. Poor milk contains 90 per cent. or more water, and has a lower specific gravity than 1.027. Such milk does not yield more than 6 to 8 per cent. of cream. Skimmed milk throws up still less cream, has a bluer colour, and is more transparent, and when undiluted with water has a slightly higher specific gravity than new milk. Good skimmed milk has a specific gravity of about 1.033, and poor skimmed milk 1.028 to 1.030. Milk purposely watered yields only 5 to 6 per cent. of cream, and invariably has a lower specific gravity than 1.025. If milk be both skimmed and watered, it yields less than 4 per cent. of cream, and possesses

as low a specific gravity as 1·025 to 1·026. A great many experiments have led me to the conclusion that within certain limits the specific gravity is the most trustworthy indicator of quality. Some of the objections to the use of hydrometers or instruments for taking with accuracy the specific gravity of milk, are based on the mistaken opinion that cream is lighter than water. This, however, I have ascertained, is not the case. Cream, I find, is lighter than milk, but denser than water, in the proportion of 1012, or even 1019 to 1000. The addition of cream, therefore, cannot depress the specific gravity of milk in the same degree as the addition of water. A low specific gravity thus always indicates a large proportion of water; at all events, I find that milk rich in butter is of a specific gravity a good deal higher than milk adulterated with even a little water. Some years ago, I made some accurate gravity determinations of pure milk before and after skimming, and of samples mixed purposely with 10 to 50 per cent. of water.

| | Sp. gr. at 62° Fahr. Before Skimming. | Sp. gr. at 62° Fahr. After Skimming. |
|-------------------------------|---|--|
| Pure milk | 1·0314 . . . | 1·0337 . . . |
| With 10 per cent. water . . . | 1·0295 . . . | 1·0308 . . . |
| With 20 per cent. water . . . | 1·0257 . . . | 1·0265 . . . |
| With 30 per cent. water . . . | 1·0233 . . . | 1·0248 . . . |
| With 40 per cent. water . . . | 1·0190 . . . | 1·0208 . . . |
| With 50 per cent. water . . . | 1·0163 . . . | 1·0175 . . . |

It appears from these results that good pure milk has a specific gravity of 1·030; skimmed milk being a little higher; and, further, that milk, having a specific gravity as low as 1·025, is either mixed with water or is naturally very poor. If the gravity should sink to 1·023 or less, it is unmistakably mixed with a considerable quantity of water. An useful instrument for approximately determining the percentage of cream is a graduated glass tube, at the top of which the cream may be allowed to collect, and its quantity may be read off. There can be no doubt about the fact that, before the late Adulteration Act, the milk of London was shockingly adulterated, and it was high time that a check should be placed upon the malpractices of milk-dealers. I am, however, anxious that the Act should not become ridiculous in the eyes of a discriminating public, for several recent milk-prosecutions have shown that the wisdom of the wise (food-analysts) in more than one or two instances is truly foolishness, even in the sight of any ordinary dairyman. I should advise rigorous prosecution in every case of flagrant or unmistakable adulteration; but whilst those entrusted with the enforcement of the Act draw the line so finely as they too frequently do at present, between pure milk and that which has been tampered with, serious mistakes must and will necessarily arise, to the discredit of all concerned in the matter, and sometimes, perhaps, to the irrecoverable loss of the reputation of an innocent man.

OBSTETRICS AND GYNÆCOLOGY.

OLSHAUSEN ON INCISION OF THE CERVIX UTERI. Professor R. Olshausen, of Halle (*Volkmann's Sammlung Klinischer Vorträge*, no. 67, 1874), considers incision of the cervix uteri, or, as he calls it, bloody (*blutige*) dilatation of the neck of the womb, a subject worthy of careful study, both because its employment is unavoidable, and because it may be dangerous if performed in unsuitable cases. Gra-

dual dilatation of the cervix is chiefly applicable to cases of pathological contraction of the canal. One has generally to deal with the relief of the milder or severer forms of dysmenorrhœa, or with the removal of sterility. Or, as indeed most frequently occurs, the two affections co-exist.

Dysmenorrhœa is divided into three kinds: that arising from mechanical obstruction, the congestive, and the ovarian. The 'gouty' and 'neuralgic' are considered questionable.

Bloody (*blutige*) dilatation is advocated only in that small class of cases under the division of obstructive dysmenorrhœa, where it is dependent upon the small size of the external os. Whether for relief of dysmenorrhœa or of sterility, the use of the knife is strongly deprecated in stenosis of the internal os, and in contraction of the cervical canal from some lesion of the mucous membrane. The operation may be followed with good results, not only where there is an absolute and distinctly pathological contraction of the external os, but also where the os is normal or nearly so. On account of the small dimensions and dilatability of the soft structures, it is exceedingly difficult to measure exactly the size of the external os, and to find out where the pathological narrowing begins. If the os be with difficulty discoverable by the finger, and if the sound, guided by a practised hand, repeatedly slip past it and at last enter with a jerk, it may safely be considered as pathologically contracted, and it is very rare to find this condition unaccompanied with dysmenorrhœa. The mere passage of an uterine sound, with a diameter of three or four millimètres, is not a proof that the os is not contracted.

If sterility co-exists with distinct mechanical dysmenorrhœa, we cannot err in assuming that there is a pathological contraction of the external os. When the removal of sterility is the object, we may even go further, and perform incision of the external os even when the mouth of the womb is quite normal. Even if a careful examination of the patient fail to detect any assignable cause for the sterility, conception may still be prevented, some unknown conditions co-existing with a normal degree of contraction of the os, which dilatation of the os might cure. The dilatation of the os by the first labour is favourable to subsequent conception; and this is further shown by the cases of women who have been sterile many years rapidly conceiving after the birth of the first child.

The assertion of West, that openings large enough to admit an uterine sound must be capable of transmitting spermatozoa, is disproved by repeated observations. How the semen enters the uterus, has not yet been made out. That conception may occur without complete sexual intercourse is true, in exceptional cases; but the conformation of the organs, the relation of the bodies one to the other, both in man and the higher animals, during the sexual act, clearly shows that the male organ should come into contact with the external os uteri.

Olshausen strongly disapproves of bilateral hysterotomes as dangerous in practice, although apparently perfect in theory. He recommends Marion Sims's blunt-pointed bistoury. The blade should be passed up as high as desirable, and a cut made from above downwards, first on one side of the cervix and then on the other. The external os should then be deeply divided, so as to leave a gaping slit. On this latter point he lays great stress, as the tendency for the parts to unite is very great. The lips are

best kept apart and prevented from uniting by tearing the adhesions down with the finger every twenty-four or forty-eight hours, and afterwards applying solution of perchloride of iron or the hot iron. Sponge-tents are condemned as liable to produce septicæmia. Laminaria tents are less objectionable. Before operating, care should be taken that no perimetritic inflammation is present.

In sterility, where there is slight antifixion with a concentrated external os, the ordinary lateral operation has seldom proved successful. The operation in these cases is modified by cutting a wedge-shaped piece out of the anterior lip.

In cases of severe catarrh of the uterus, it is advised to perform the bilateral operation, as the wider and larger the orifices are, the easier is internal medication; still, on account of the danger, it should be strictly limited to the most severe forms.

Finally, incision of the cervix must be accepted as an established therapeutical remedial measure, requiring, however, the greatest care in the performance and in the after-treatment. The author believes it is too frequently performed for trivial affections, and in a most reckless way. Such practice he can not too strongly condemn, as most unjustifiable.

WERNICH ON THE COURSE OF SEVERE LUNG-AFFECTIONS DURING PREGNANCY.—Dr. A. Wernich (*Beiträge zur Geburtshilfe und Gynäkologie*, vol. ii. part 3, 1873) believes, from his own experience, that phthisis runs a milder course during gestation; while the reverse is the case during the puerperal state. In acute pneumonia, the excess in mortality arises from the pressure of the gravid uterus on the diaphragm impeding the movements of respiration and retarding the circulation of the blood through the lungs, throwing more strain on the right side of the heart. In pneumonia, death takes place chiefly from insufficiency of the heart, and in pregnant women with the appearance of oedema of the lungs, according to Jürgensen (*Sammlung Klinischer Vorträge*, no. 45), emptying the uterus of its contents would, by relieving the pressure off the abdominal vessels, cause an increased flow of blood to the heart, coupled with the freer movements of the diaphragm, burden the right side of the heart still more, and augment the oedematous state of the lung. The treatment is to strengthen the contraction of the heart by the internal administration of digitalis, and unloading the right side of the heart by venesection, when the dyspnoea and distress are intense. The author relates two cases where he extracted blood; in one by venesection, in the other by cupping. In the first case (venesection) the relief was immediate, the patient falling asleep directly. In both it seemed to induce labour, signs of uterine contraction being present before the operation. Living six months' children were brought, by the aid of instruments, into the world. In the case of venesection the patient shortly afterwards collapsed and died. In the other, the patient wandered in her mind, saw strange figures, exhibiting the usual symptoms of mania from anæmia of the brain. Digitalis and stimulants were given with good results, the patient making an excellent recovery. In a third case, blood was not extracted; sinapisms and water compresses alone being used, with the administration of digitalis. The patient did well, without miscarrying. Seeing that extraction of blood brought on miscarriage, the object to be avoided, the question is, should it be done? The writer believes in all cases where the symptoms are very

urgent and not relieved by other treatment, the proper course is to bleed (Gusserow mentions a case where the result was good without bringing on labour); and in case of collapse, to transfuse blood from the arm of another. That both children were born alive, he wishes particularly to note.

LÖWENTHAL ON DISPLACEMENT OF THE UTERUS. Dr. Wm. Löwenthal (Heidelberg, 1872) maintains that all displacements of the uterus arise primarily from some change in the tone, either of the vaginal walls, causing versions, or of the structure of the uterus, producing flexions.

Versions arise from a relaxation of the opposite vaginal wall; anteversion from the posterior wall becoming slackened; retroversion, *vice versa*; and so with the other versions. The author proposes to cure these conditions by shortening this relaxed wall—Simon's operation of colporrhaphia. For the relief of flexions, the uterus is to be pulled down an inch, to allow the invaginated portion of the cervix to be compressed by the vaginal walls, being kept in position by means of a ring pushed over it. In an anteversion, the uterus is to be drawn down by catching hold of the posterior lip of the os and uniting the posterior wall of the vagina to the posterior wall of the uterus, so as to drag the uterus back—and so forth with the other flexions. The writer has not performed any of these operations on the living subject.

W. C. GRIGG, M.D.

HIGHMORE ON AN OVERLOOKED SOURCE OF BLOOD-SUPPLY FOR TRANSFUSION IN POST PARTUM HÆMORRHAGE.—Dr. Highmore, in a communication to the *Lancet* (January 17), refers to the occasional difficulty, especially in country practice, of procuring blood for transfusion in cases of *post partum* hæmorrhage, in which the only chance of saving life would be by performing that operation. Having narrated a case in point which proved fatal, and in which no 'blood-donor' could be found, he suggests that in similar cases the blood which the patient has lost should be collected, defibrinated, warmed to the proper temperature, and then injected. The editor of the *Irish Hospital Gazette* says, 'The suggestion to use the blood lost by a patient for transfusion purposes, is not a new one. In December, 1871, Dr. Robert McDonnell, at a meeting of the Dublin Obstetrical Society, alluded to the case of a man whose limb had been torn off, and who had arrived at hospital, after coming a long way from the country, exhausted from loss of blood, so that he sank two days after the operation of amputation. In such a case, Dr. McDonnell suggested that the patient's own blood, unavoidably lost at the operation, should be defibrinated, and then, after the operation, given back to him. Such a procedure would, we opine, be much more feasible in a surgical case than in a midwifery one, as the blood which is lost in cases of *post partum* hæmorrhage is usually exuded from the vagina in the shape of large, solid clots, in which the blood-corpuscles are entangled in the fibrin, forming masses which it would be difficult to liquefy, even with the addition of (to which Dr. Highmore has not referred) an alkaline solution.'

MISCELLANY.

SMALL-POX caused twenty-one deaths in Vienna in the week ending February 26.

PROFESSOR DU BOIS REYMOND lately received an invitation to a professorship in Geneva; he has, however, decided on remaining in Berlin.

DR. KÖSTER, Professor of Pathological Anatomy in Giessen, has accepted an invitation to the analogous chair in the University of Bonn, in place of Professor Rindfleisch, who goes to Würzburg.

We understand that Miss Elizabeth Morgan, M.D., one of the physicians at the Hospital for Women, Marylebone, is about to follow the example of her colleague Mrs. Anderson, M.D., by entering into the bonds of matrimony. Her future husband is a physician, by name Dr. Hoggan.

M. CRUVEILHIER, honorary professor in the Faculty of Medicine of Paris, and author of the well-known and excellent work on anatomy, died a few days ago at his residence near Limoges. He was eighty-three years old.

THE GERMAN SURGICAL CONGRESS will assemble in Berlin next month. A preliminary meeting for the purpose of formal reception will take place at the Hôtel du Nord on the evening of April 7, and the business will be transacted on the following four days. There will be a discussion on the treatment of wounds, with direct reference to Lister's method; and, if sufficient materials shall be at hand, there will be a series of communications on the return of cancer after removal. It is also proposed to have an exhibition of preparations, instruments, apparatus, &c., on a larger scale than has hitherto been the case.

CONTAGIOUSNESS OF SCARLET FEVER.—Sir Thomas Watson, Bart., M.D., writes to us:—I venture to ask whether it was prudent to republish, in the MEDICAL RECORD, the opinion of Dr. Snow, of Providence, Rhode Island, that scarlet fever 'is not contagious in the ordinary meaning of the word.' Surely the collective mind of the profession in this country has long been made up that genuine scarlet fever is *catching*; a popular word which comprehends any and every way in which that dreaded disease may be communicated from one person to another who has not already had it. To disturb this conviction in the minds of parents, schoolmasters, and inexperienced practisers of medicine would, in my judgment, be a most perilous mistake.

THE CHAMELEON.—M. Paul Bert has undertaken a very interesting series of researches on the mechanism of the changes of colour of the chameleon. They depend entirely on the action of the nervous system; by exciting emotions of fear, passion, avidity, he produced changes from black to yellow, blue, violet, and rose-colour, in very short space of time. These changes were not affected by arresting the blood-supply to a limb, but were immediately stopped in any part by dividing the nerve which supplies it. The complete independence of the two eyes (which is very observable in watching the chameleon), was tested by suddenly awakening it by a light held before one eye, when the corresponding side of the body immediately changed colour, each side of the body assuming another tint when it awoke in turn. The two luminous perceptions were different, and the difference of coloration shows the difference of the impressions on the nerve of sense.

THE ACADEMY OF SCIENCES IN PARIS.—The following examinations have been made for the vacancy in the section of medicine and surgery, caused by the death of M. Nélaton:—1. M. Gosselin; 2. *ex aquo*, MM. Broca, Demarquay, and Rochet. The eminent physiologists, MM. Marey and Vulpian, have also offered themselves as candidates, and a minority of the committee of nomination decree that their names should be submitted for election. The *Gazette Médicale de Paris* justly remarks that it is time to make an alteration in the arrangement which, however appropriate it was fifty years ago, is now no longer so, by which the only section open to anatomists and physiologists is that of medicine and surgery. At every election to the section there is a contest between the anatomists on the one hand, and the physicians and surgeons on the other. Physiology, or rather biology, ought to be represented in a special section.

HOUSEHOLD DISINFECTION.—Dr. M. J. MacCormack, Medical Officer of Health, for Lambeth, writes: With many of my brethren of the medical profession, I have seen with much pleasure in your columns, that it is proposed to work 'Baker's Patent Disinfectors' on a large scale in the form of a limited company.

I do not pretend to judge of the commercial aspects of the company, but to the sanitary results they will have it in their power to achieve, I can from actual experience confidently testify; especially, amongst others, I can refer to a public institution in this district, where for years there were several cases of epidemic disease, the result of the escape of sewer-gases, and where since, on my advice, the apparatus was fixed, there has been entire immunity from such cases.

I may further add that a manufacturer employing 200 hands in the neighbourhood of Cheapside, and who had repeated complaints from the local sanitary authorities, adopted the patent with the most satisfactory results.

The co-operation with the company of Mr. Ernest Hart leads me to hope that an energetic effort is about to be made in a practical shape to arrest and stamp out all those diseases the product of impure gases.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MARCH 25, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

WYMAN ON THE BRAIN OF AGASSIZ.

This remarkable man was so well-known for his intellectual labours, that all facts relating to the condition of his brain will have a peculiar interest. The *Detroit Review* takes the following from a report of the necropsy, by Dr. M. Wyman (*Medical and Surgical Reporter*, February 7). The walls of the skull were thick and heavy. The dura mater was very adherent to the skull, and remarkably thick. The veins of the arachnoid were thickened. The cerebral sulci were deep and wide. There was extensive disease, calcification and atheromatous degeneration, of the arteries at the base of the brain. The basilar artery was the continuation of the left vertebral, the right vertebral being represented by an exceedingly small vessel which united the basilar with the inferior cerebellar. In the left vertebral artery, one-half inch below the anterior edge of the pons Varolii, was a reddish yellow opaque friable plug completely obstructing the vessel; still lower, was another more recent plug. The first was one-quarter of an inch long, the second four inches. The weight of the entire brain was 53·4 avoirdupois ounces. Allowing one ounce diminution in weight of the brain for each ten years after thirty-five, the greatest weight of Agassiz's brain may be estimated at 56·5 ounces. It will be of interest to compare this weight with that of some other brains. We take from Flint on the nervous system the following facts.

Cuvier died at sixty-three, his brain weighed 64·33 ounces; Abercrombie died at sixty-three, his brain weighed 63 ounces; Ruloff died at fifty-three, above medium stature, executed for murder in 1871, well versed in several languages, his brain weighed 59 ounces; James Fisk died at thirty-seven, illiterate, but said to have had great executive ability; his brain weighed 59 ounces. A boy, thirteen years old, died from injuries caused by a fall; his brain weighed 58 ounces. He had been a very healthy and intelligent lad (*British Medical Journal*, October 19, 1872). In the same journal, December 24, 1872, Dr. Tuke reports the brain of a congenital epileptic idiot as weighing 60 ounces. The skull was unsymmetrical, and the cerebellum deformed. In the same journal, October 26, 1872, Dr. Morris reports the heaviest recorded brain. It exceeded 67 ounces. It was taken from a man who died of strangulated hernia. The man was thirty-eight years old, robust, and a bricklayer by profession. He was 5 feet 9 inches high; was fond of drink, had a good memory, was fond of politics, but could not read or write. From this short list, it will at once be apparent that mere size or weight of brain does not necessarily indicate the intelligence of its possessor.

STEARNS ON THE TREATMENT OF FRACTURES.

Dr. J. H. Stearns, of Milwaukee, writes as follows in the *Detroit Review* for February, 1874.

Many ingenious contrivances have been invented to keep fractured limbs in position during the forty days and forty nights required to form a provisional callus and render artificial support unnecessary.

I long ago discarded the use of weights or pulleys, screws or springs, for purposes of extension in fractures, and have come to consider them as instruments of torture, and altogether useless if not positively detrimental. In the hospital where I now am, I have had as many as six fractures at one time, every one of which, except a fractured clavicle, was treated by compression alone.

Allow me to describe, in a few words, the treatment and dressing for a fracture of the middle of the thigh. Four pieces of wood, say three-eighths of an inch thick, are cut as long as can be applied without involving the protuberances at each end of the shaft, each a little less in width than one-fourth of the circumference of the limb, and tapering to conform to the shape. These are padded with wadding secured by a roller bandage.

Let an assistant hold the limb, as near in its normal position as may be, place a splint under, one on each side, and one on top of the limb; with a tape, passed around in a loop, tie at the centre, another at each end, two more between; by this time you can tighten the centre one, then the ends, and so on, until by reducing the size of the limb, it corresponds in length with its fellow.

No pulling is necessary, but the fragments readily come into apposition; and if the lower fragment be held in proper position, the fracture is thus painlessly reduced—you then have the limb under the most complete control—if it swells, as it always will, you can loosen the tapes with no bandages to unwind. It is never required to have it tied so tight as to impede the circulation; and, if care be exercised during the whole time to have just pressure enough to keep the limb extended, little discomfort is experienced by the patient, and a good recovery results with the smallest amount of shortening.

The same plan applies equally well to the leg or arm. This method is presented not as a theory, but as the result of actual practice.

As to fractures of the clavicle, no person can bear a pad in the axilla, as a fulcrum, with the humerus as a lever. The indications are to carry the shoulder upwards, outwards and backwards. This is easily accomplished by placing the hand of the injured side on the sound shoulder, and placing a broad bandage around the neck and the point of the elbow.

TOXICOLOGY.

ON POISONING BY VANILLA-ICE. BY DR. L. ROSENTHAL.*

I come before you with the open confession that, in spite of all the trouble I have taken, I have not succeeded in solving the problem of poisoning by vanilla-ice. The chemical investigations carried on

* Read before the Berlin Medical Society. (*Berliner Klinische Wochenschrift*, March 9, 1874.)

under my direction, by order of the president of police, by Dr. Schädler, have shown that the hitherto most current and plausible hypothesis—that the poisoning is to be attributed to cardol—is untenable; but experiments which I have made in conjunction with that gentleman on rabbits and cats, have had a negative result. We fed the animals with decoctions both of the pod and of the pulp of vanilla; we repeatedly administered to them vanilla-ice obtained from the Vienna *café*: in all cases, the animals subjected to experiment remained healthy, and showed no condition varying from the normal state. Under these circumstances, I have thought it my duty to bring the subject before this Society, hoping that my communication will be followed by a discussion, by which some light will be diffused over the obscurity in which poisoning by ices has hitherto been shrouded.

In my opinion, poisoning by vanilla-ice is not so very rare as is generally assumed, especially when we consider that vanilla-ice is not one of the articles of food in every day use. Cases of poisoning of this kind were, within my knowledge, first observed and described by Orfila, in Paris, more than twenty years ago; and in that city cases of poisoning by ices have repeatedly come under notice from time to time. Similar observations have been made, in some other places on several occasions—in Vienna, in Munich, in Leipzig, in Amiens, in Erlangen, Altona, and Bergen. Here also, in Berlin, cases of poisoning by vanilla-ice have occurred more than once; but whether they have been described, I am not aware.

All these cases of poisoning have this peculiarity, that they always have one starting-point; all, or, I will say, nearly all the persons, who at a certain time eat vanilla-ice in a certain *café*, become ill; while other persons in another place do this with impunity. Here in Berlin, in the last days of August, 1873, an endemic of this kind prevailed; all the persons, who at this time ate vanilla-ice in the Vienna *café*, suffered from more or less severe symptoms. I was in the position of being one of the first to observe the cases of illness, and to trace them to poisoning by ice.

Allow me to relate my first observation somewhat in detail, as I shall be thereby enabled to set forth the symptoms, the duration of the illness, &c.

During the night of August 26-27, I was called to a family, in which I was attending one of the daughters in the last stage of phthisis; I had visited on the evening of the 26th. With the exception of the consumptive patient, all the family, consisting of the father, mother, and two other daughters, were in perfectly good health. The messenger told me, that nearly the whole family had cholera. Even though, as you know, cholera was prevalent here at the time, the simultaneous and sudden attack of the whole of the members of a family was rather extraordinary; and the next idea that occurred to me was, that it was a case of poisoning. On inquiry, I was informed that the patients had eaten ices in the *café* in the evening. As, so far as we know, it is only vanilla-ice that causes poisoning, I made inquiries as to whether they had taken vanilla-ice, and found that they had done so. In this way, I entered the sick chamber with a diagnosis already surely made.

The mother and one of the daughters had each eaten a portion of vanilla-ice about 10 p.m. They had taken a third portion home, and had divided it into two equal parts. Of one of these the father ate two teaspoonfuls, and gave the remainder to his consumptive daughter; the third daughter ate the other

half; and a little old dog licked the one plate that was used. All the members of the family, including the dog, were taken ill during the night. At 11 p.m. the eldest daughter began to vomit, and violent diarrhoea soon afterwards set in; half an hour later, the same symptoms showed themselves in the mother, and the remaining members of the family followed. It is to be observed, that only the two healthy daughters slept together in the same room; all the other patients had separate bed-chambers. On the whole, the severity of the symptoms was in proportion to the quantity of the ice taken; so that the mother and eldest daughter suffered most; the father least. He had vomiting and diarrhoea twice only; then followed the phthisical daughter, and finally the third daughter and the mother. As no notice was taken of the dog during the night, I cannot say when the symptoms of disease began in it; but the next morning we found the room extensively soiled with vomited matters and fæces, and the symptoms continued through the whole of the next day. The animal refused food, did not come when his master called him, and showed by his behaviour that he was in great pain. The evacuations on the second day consisted mostly of whitish mucus.

I return now to the human subjects. The symptoms in the mother and one of the daughters were so violent, that they nearly completely assumed the form of cholera. Vomiting followed vomiting, stool followed stool. To these were added violent cramps in the calves of the legs, coldness of the extremities, lividity of the limbs and of the face, and the pulse could hardly be felt. Under these circumstances, I am not surprised that other colleagues, who had not the opportunity of observing these cases of illness in the greater number of members of a family at the same time, have diagnosed the disease to be cholera or cholerine. I will, however, remark that, both those who were most severely attacked had violent gastralgic and enteralgic symptoms, and that the pupils (as also in the other cases which I have observed) were moderately dilated, and were slow in responding to the stimulus of light.

The duration of the illness was greater or less according to the severity of the symptoms. The mother was quite well, with the exception of some weakness, on the fourth day.

The prognosis, from the observations already made, was favourable; for, hitherto, no case of death from poisoning by vanilla-ice has come to our knowledge.

In the same night, several quite similar cases occurred. I will here briefly relate those which have come to my knowledge. Herr Güterbock, senior, was kind enough to send me one of his patients after recovery. He and his wife had suffered from the same symptoms as have been described above. It is remarkable, however, that this gentleman suffered for some time from a painful sensation as of burning, in the mouth and throat. In these parts, a number of red and inflamed spots were seen on the third day; and, at the time, I was inclined to attribute them to the action of cardol, which, according to Schroff, acts even more energetically than cantharidin. This observation in the meantime stands alone; in the other cases I observed nothing of the kind.

Three other cases were observed on the same night by Herr Riedel, in a family which had eaten vanilla-ice. As, however, Herr Riedel declared the patients to be suffering from cholera, and at the

present day asserts that this was the disease, I will make no further comment on his cases. The patients recovered.

A day later, another case came under my observation. The patient had eaten some ice about 2 p.m., after his dinner; at 5 o'clock he was taken ill, but recovered the next morning. Finally, two other cases came to me in the night of September 1 and 2.

Similar cases were communicated to me by Messrs. B. Fränkel, Steinauer, Danziger, O. Simon (who himself was poisoned), J. Meyer, Citron, and Oppenheim. Besides these, I have heard of a number of cases through the public; among them I will mention a family in the Chausseestrasse, of which all the eight members were taken ill in one night.

It would be interesting to determine how many persons altogether became ill at this time from vanilla-ice, and how many escaped in spite of its use. In the meantime, this remains a *pium desiderium*. The discussion will perhaps afford some further information.

I come now to the question: Wherein lies the source of poisoning by the use of vanilla-ice? We may here reasonably take three possibilities into consideration. The symptoms may be caused: 1. by cold; 2. by the materials constituting the frozen substance; 3. by other injurious substances accidentally introduced.

Regarding ice as such, we know well that its use may be followed by gastric catarrh and other slight stomach disorders, but it is not known that symptoms resembling those of cholera follow its use. Further, the following fact is opposed to this idea. Symptoms like those which I have already described have never yet been observed to follow the use of fruit-ices; and among cream-ices it is, as far as our knowledge extends, only vanilla-ice that has produced symptoms of poisoning.

I here beg leave to remark, in passing, that fruit-ice is prepared with sugar and the acid of lemons, to which the desired fruit-juice is added; while, in the preparation of cream-ice, eggs and cream are used, and the flavour is given by adding vanilla, chocolate, &c. Besides these, the various kinds of cream-ice are boiled before being introduced into the freezing vessel, which is not the case with fruit-ice.

While we must exclude the cold mixture as such from suspicion as the cause of the severe symptoms of poisoning, we succeed no better when we take into consideration the materials accidentally introduced into the ice. The most careful chemical examinations have given the following results. Most frequently (as in our case) traces of lead are found, now and then more or less iron, and in two cases there were not inconsiderable quantities of tin. As we may exclude the lead and iron (the former on account of its small quantity) from suspicion as the causes of illness, there remains only the tin; and, in fact, Green, who made a chemical examination of the ice which led to poisoning in Altona, has expressed the opinion that the tin combines with the lactic acid formed from the cream, forming a lactate of tin, which acts as a poison on the organism. The experiments, however, which Maurer of Erlangen has made with tin on animals, have shown the complete harmlessness of this metal. I will finally remark on this subject, that in our case the vessels used in the preparation of the ice were found to be in a faultless and thoroughly clean condition. The ingredients were boiled in well tinned copper vessels, and the

freezing was carried on in clean porcelain cylinders.

With regard to the materials used in the preparation of the ice, I have already mentioned the milk. Whether eggs can give rise to symptoms of poisoning is unknown to me; and thus we come to the only remaining possibility, that the poisonous agent is contained in the vanilla-pods. Up to the present time, we cannot furnish certain evidence on this point. The idea is opposed by the fact that, though vanilla is extensively used in the preparation of tea and chocolate, as well as of sauces and soups, which only differs from vanilla-ice in containing greater quantity of milk and in being of a higher temperature, the use of these has never been observed to be followed by symptoms of poisoning. We cannot regard any of the substitutes for vanilla, such as balsam of Peru or storax, as the vehicles of the poison, since in all the known cases it was really vanilla that was used in the preparation of the ice, and neither Peruvian balsam nor storax can be reckoned among poisons.

I must on the other hand mention a circumstance, which in my opinion gives incontestable evidence that the poison is contained in the vanilla-pods. Cases of poisoning by vanilla-ice occurred in a confectioner's shop in Altona. The proprietor of the shop was in consequence obliged to give up his business; the vanilla-pods in his store went into the possession of a confectioner in Bergen—and the ice made with these pods proved to be poisonous.

I now hold, with many others, the opinion that the symptoms of poisoning produced by vanilla-ice must be placed to the account of the vanilla-pods; but the endeavours to ascertain the poisonous agent have hitherto been in vain. Martius believed that he had found it in the crystals covering the pods, since he observed, that the pods gathered in the East Indies were covered with crystals of a different shape from those on the pods imported from Mexico. In our case, the pods had no crystals at all. Schroff, who had occupied himself with the subject most thoroughly, has put forth three hypotheses, of which he holds the first to be most probable. 'In Columbia,' he says (*Lehrbuch der Pharmacognosie*, 2nd ed., 1869), 'the pods are greased with the fatty oil from the seeds of the *anacardium occidentale* (cashew-nut) and dried in the sun. As a very acid juice is contained between the endocarp and ectocarp of this fruit, it is possible that, in preparing the oil from the seeds without sufficient care, this, and the vanilla-pods over which it is rubbed, may become contaminated with the acid juice; and that in this way the occasional occurrence of poisoning after the use of vanilla-ice may be explained in these cases, where no other injurious condition can be ascertained.' In another place (*Wiener Medizinische Wochenschrift*, no. 82, 1863) he says that experiments on rabbits with cardol prepared from this oil have shown that it is capable of producing the symptoms observed in patients.

Setting aside the fact that other observers make no mention of the rubbing of vanilla-pods with the cashew-nut oil, Schroff does not show that the cardol used in the experiments was derived from vanilla-pods. Thus his hypothesis loses probability; and Dr. Schädler has been informed that there was no cardol in the vanilla-pods obtained from the Vienna café.

The second hypothesis which Schroff put forth, and to which he himself attached little weight, is the following. In the vanilla-fruits, on careful micro-

scopic examination, there are found in the parenchymatous cells of the mesocarp packets of sharp-pointed needle-shaped crystals, which were very large in the vanilla used in preparing the ice in question; and, according to Soubeiran, they act like nettles on the skin. These must act as mechanical irritants; but in the ice examined, they were always in a broken-up condition.

Finally, whether any of the fatty acids formed under certain circumstances may be the cause of the poisoning, must remain undecided—as yet, there is no proof of such a cause.

In conclusion, while I thank those who have assisted me by contributing facts and by searching through the literature of the subject, I must guard myself against being supposed to advance a new hypothesis. I abstain from this the more, as the necessary knowledge is wanting to me. But there is one thing to which I may direct attention. Not to mention that the various kinds of vanilla differ much in quality, I have found it stated by Schroff alone that the pods are gathered when ripe. All other authors state that they are gathered in the unripe state, and prepared in many ways for use. I here add what Henkel (*Handbuch der Pharmacognosie*, Tübingen, 1867) says, from Von Müller's travels in Mexico. He first describes vanilla as the dried unripe capsules of the *Vanilla planifolia*; then gives the following account of its preparation. 'The Indians of Misantra collect the vanilla in the mountains and forests of Quilates; the fresh capsules contain an acrid viscous juice, which protects them against insects. The Indians, who only betake themselves to the forests for eight days at the time of the gathering, often sell the raw fruit to the colonists, who then prepare and dry them, and tie them in bundles for sale. In Misantra, the most usual way of drying the vanilla is to spread the shrivelled yellow fruit on linen in the sun for some hours. When the pods are sufficiently heated they are wrapped in woollen cloths, where they soon assume a dark copper colour; they are then exposed to the sun from morning to evening until they are dry. When the use of the sun is prevented by continued rain, artificial heat is employed; frames are made of reed or bamboo, which are suspended by cords at the four corners and covered with woollen cloths, on which the capsules are spread. These frames are swung over a fire which does not smoke, until the pods are dried. . . . In the State of Oaxaca the natives dry the vanilla by piercing the capsules all over with needles, so as to allow the escape of the viscous juice.'

Flückiger (*Lehrbuch der Pharmacognosie des Pflanzenreichs*, Berlin, 1867), expresses himself in a similar way, though not with so much detail. 'In the second year, the fruit buds ripen into an entirely non-aromatic pod-shaped fleshy capsule, with a viscous milky juice, and opens longitudinally in two unequal valves. It is not allowed to become fully ripe, but is collected when its green colour is beginning to pass into brown, and is dried, according to some accounts, in a very elaborate manner, inasmuch as it is subjected to heat either exposed, or wrapped in woollen cloths; under this treatment it ripens, and first develops the aroma and the favourite dark-brown colour of the commercial fruit.'

From these statements, is it difficult to imagine that in some of the pods—and, as far as we know, it is only individual pods that are poisonous—the process of artificial ripening is not complete, and that it is the unripe pods which produce the symptoms? I

content myself with having called attention to this question. May those who are more skilful decide it!

[The reading of Dr. Rosenthal's paper was followed by a discussion, a report of which is given in the *Berliner Klinische Wochenschrift* for December 22, 1873.]

Dr. B. Fränkel said that, as his name had been mentioned, he would give fuller information on the cases of poisoning observed in his family. Several persons were taken ill, nearly in the proportion in which they had partaken of a certain dish. The symptoms were those of vanilla-poisoning, such as had just been described by Dr. Rosenthal. One person alone of the household, who did not eat any portion of the dish, remained unaffected. The dish in question was a warm farinaceous preparation, to which vanilla was added in preparation. It was made in a porcelain vessel, and was so simple in composition, that the illness could only be attributed to the vanilla. He had given to Dr. Liebreich for examination some vanilla-pods, obtained from the same dealer, and taken from the same packet as those which produced the poisoning.

Dr. Veit said that, in the nights of August 28 and 29, he observed a case of poisoning with vanilla-ice. He took special notice of the fact, because a female friend of the patient (a woman) who had eaten of the same ice, was taken ill with similar symptoms. The symptoms were those of cholera, but the gastric pain was of longer duration, and recovery slower.

Dr. Kalischer on the same night saw a similar case of illness in a lady who had eaten some ice in the Vienna *café*. One of her children also ate of the ice, but was not ill. The symptoms were very severe, and the consequent prostration lasted several weeks.

Dr. Henoch was able to give particulars of a former series of cases of poisoning, in which he was one of the victims. At an evening party there were various ices, obtained from one of the first confectioners in Berlin. Dr. Henoch ate some vanilla-ice; and four hours later was taken ill. His evacuations were colourless, and quite resembled those of cholera, which was not epidemic at the time. On the other hand, he had no pain in the stomach or bowels, a circumstance which spoke against metallic poisoning. In the same night, a young girl and fourteen other persons of the same party were taken ill with similar symptoms; they had all eaten vanilla-ice. Those who ate other ices were not attacked. In his own case, the diarrhoea lasted four hours; no changes in the pulse or in the temperature were observed. On applying to the confectioner, he was assured that vanilla-pods of the same kind had been used for some months without producing poisoning. The pods shown to him were abundantly covered with crystals. It was remarkable that the symptoms were specially severe in those persons who had eaten the portions of ice nearest to the containing vessel; especially the servants, who scraped it to obtain the portions of ice that adhered to it. In these the symptoms were so severe that death was feared. This circumstance appeared to indicate metallic poisoning.

Dr. Schiffer remarked that, in consequence of the high price of the vanilla, it frequently underwent falsification in trade, especially by the substitution of other pods like those of the vanilla. The possibility of poisoning from this source must be borne in mind.

MEDICINE.

BETZ ON A CASE OF VOLVULUS, TREATED BY (EXTRA-PERITONEAL) ABDOMINAL SECTION; BREAKING DOWN OF A FALSE LIGAMENT BY MANIPULATION; RECOVERY.—This interesting case will be found in detail in Betz's *Memorabilien*, vol. xviii. p. 493. The author, Dr. Friedrich Betz, insists strongly upon the importance of a careful examination of the abdomen by percussion and palpation, as soon as we are called to a case of intestinal obstruction. When this is done at an early date, we can generally learn the most tender spot, and the starting-point of the symptoms of obstruction. This information is of great value, not for mere diagnostic purposes, but as a guide, should we subsequently determine upon operation. If called too late, or if we defer this examination too long, it is very difficult, if not impossible, to determine either the site or the kind of the obstruction with which we have to deal, or to feel justified in recommending an operation. Of late, very great progress has been made in the differential diagnosis of cases of internal obstruction of the bowels; and it is to be hoped that abdominal section will be done more frequently, and at earlier periods than heretofore. The following history affords material for more hopeful prognosis in such cases.

A woman, aged thirty-five, had suffered for some years from femoral hernia of the right side. When she was three months pregnant the rupture became incarcerated, but was reduced without any very great difficulty. During the remainder of gestation it gave her no further trouble, and was not even visible. A month after delivery (the night of July 17-18, 1870) she was seized with violent abdominal pains and eructations. Flatus and fæces no longer passed by the bowels. On the 19th Dr. Betz saw her, and found the right hypogastric region tense, convex, distended, and very tender to touch. The left side of the belly was somewhat sunken in, and not at all tender. Fæcal vomiting had set in. The other symptoms remained as before. Over the swelling the percussion-note was dull; elsewhere normal. The pains extended to the loins, and were remittent. There was no external sign of the old hernia. Digital explorations of the crural canal gave great pain. Three possibilities presented themselves; viz. perityphlitis, internal obstruction (from a twist in the bowel), or strangulation in the crural canal. The globular form and board-like hardness of the swelling were against perityphlitis, whilst all the symptoms favoured ileus. The former history and the local tenderness rendered it probable that there was a Littré's hernia, but this tenderness was afterwards found to be only part of the general sensitiveness to pressure. Morphia was given in half-grain doses every six hours. Cold compresses were applied, and water and ice given freely, but purgatives were religiously avoided. Next day (July 20) she was worse; there was less tenderness, but no improvement in either the local or the general symptoms. Pulse 100. Her countenance was anxious. The ileus had now lasted three whole days. Dr. Betz could see no other means of doing good, except abdominal section, with the view either of breaking down a false ligament (band), or of relieving the possible strangulation in the crural canal by withdrawing the coil of intestine from within. After giving chloroform, he made an incision two inches long through the skin, over the crural canal, in a line be-

tween the anterior superior spinous process of the ilium and the spine of the os pubis. The fat and fasciæ were divided partly by forceps and knife, partly pushed aside by the fingers. The external crural ring was found to be quite clear. The abdominal wall was then divided down to the peritoneum. Before opening this, he tested the resistance and mobility of the coils of intestine, using a little gentle force. The patient and himself were conscious of a very evident crack or snap, as if some fibres had given way. He was now convinced that the volvulus was produced by a false ligament, situated in the pelvis (horizontal ramus of the pubic bone), and, since one end had given way, it was now possible for the bowel to untwist, and for its patency to be restored. The peritoneum was therefore not opened, but the wound was closed with a compress, and the cold applications were continued. Shortly after the operation, both pains and vomiting ceased. On the 21st, the swelling in the right side was still perceptible, but less tense. Her general condition was improving; she had no thirst. Pulse 80. No fæces or flatus passed. Clysters of Glauber's salt, and milk and water diet were ordered. On the 22nd, flatus and a fairly copious, thin, offensive evacuation passed. The tumour was still perceptible, but less tender, flatter, and less elastic. The wound was already more than half healed by the first intention. Her general condition was good. Pulse 80. The clyster was repeated. On the 23rd, the bowels acted pretty freely. On August 15 the wound had healed nicely. Further treatment was simply precautionary, as to diet and regimen. On August 31 she still had slight pain when she lay on her left side. She felt a kind of ball in the original spot; and there was frequent gurgling there, as of gas passing through narrow into wider portions of bowel. Deep pressure in the right hypogastric region gave rise to resistance, and one spot was still tender.

It can scarcely be doubted that, after the breaking down of the false ligament, time was still necessary for the untwisting and gradual restoration to health of the agglutinated and convoluted intestines. Hence the subsequent symptoms. Now that three-and-a-half years have elapsed, she is free from all distress, and has no sign of any hernia. The firm cicatrix, adherent to the abdominal muscles, fulfils the functions of a truss. Dr. Betz modestly attributes this successful result to improved methods of diagnosis and recent additions to our knowledge of the etiology of such cases; and remarks that if 'delays are dangerous' in external herniæ, they are still more so in internal obstructions.

KULISCHER ON A CASE OF ABDOMINAL ANEURISM.—In the *Berliner Klinische Wochenschrift*, nos. 8 and 9 (February 23 and March 2, 1874), there is a very interesting clinical history of a non-commissioned officer, a saddler and harness-maker in the Russian Cavalry (Guards), aged thirty-three, Feodor Chapugin by name, from which we extract the following notes. The author, Dr. Kulischer, is surgeon to the Peterhof military hospital at St. Petersburg. The patient first entered the hospital on January 29, 1872; and Dr. Znamjenski, under whose care he then was, stated that he was 'much emaciated, very pale, and anæmic.' He had symptoms of chronic gastrointestinal catarrh, and complained of pains in the lower part of the abdomen, having suffered for some years from these, and from constipated bowels. His pulse was weak and small, not rapid. The respira-

tory organs were healthy. Under simple treatment, he recovered sufficiently to leave the hospital and resume his duties at the end of February. On January 20, 1873, he was re-admitted; this time under Dr. Kulischer's care. In addition to the abdominal pains, he now complained of feeling a hard body move about in his belly, which, when he stood up, seemed to press upon the left inguinal region; during dorsal decubitus, however, it pressed upon the umbilical region, for the most part on the left side, but very often on the right of the navel, particularly if the patient lay towards the right side. On rising up the patient felt queer, even to faintness, vertigo, and loss of consciousness. He attributed all these symptoms to a left inguinal rupture, and therefore wore a truss on that side. He accounted for the origin of this 'rupture' in this way:—the pains in the lower belly had lasted fifteen years, but had become very much worse in 1872, after he had, during his work, pressed a solid body against the front of his abdomen, and pushed this back against the vertebral column. Violent palpitations of the heart ensued, then the queer feelings, and finally the sensation of a solid body moving about towards the left hypochondrium. Seven days before admission all these symptoms, viz. the faintness, giddiness, and trembling when he stood upon his feet, or remained upright any length of time, had been much aggravated by carrying a weight of little more than 15 lbs. a short distance. This history, and the absence of any reliable symptoms of hernia, gave rise to the opinion that he suffered from an abdominal aneurism, which was justified by the following objective symptoms. 1. To the left, and a little above the navel, the ear alone, or assisted with the stethoscope, plainly heard a whizzing, or for the most part bellows-like, bruit. The eye and touch both verified a strong pulsation, which lifted high the left umbilical region synchronously with the pulse, the movement being chiefly in the vertical direction. This very spot was the site of the most intense pain. 2. When the pulsating spot was compressed with the flat hand, and supported from below and from the front, the patient could assume the vertical position without any of the giddiness, &c.; or, if the pressure were slight, he had slight symptoms. On removing the hand, the radial pulse sank almost to nothing. It became fuller again, and as strong as before, when the patient lay down, or on again making pressure on the pulsating spot, even when he stood upright. Further observations (January 22-31) gave the following results. He suffered from constipation, better relieved by purgatives than by enemata. The result of digital exploration of the rectum was negative. External pressure, even of a bandage, made the bellows-murmur louder and clearer. Compression of the aorta above the navel stopped both the murmur and the pulsation; the latter was usually strongest to the left of the umbilicus. Both femoral pulses, particularly the left, were weaker than the radials, which, in the absence of the faintness, &c., were stronger and fuller than his weak state would have led one to expect. When he was recumbent, the cardiac sounds, breath-sounds, and rhythm of both circulation and respiration, were perfectly normal. The patient had some of his attacks of faintness during the first three days after admission; and again on January 28, whilst standing to urinate. The same evening, at 10 p.m., 'he felt as if something was torn away to the left of the navel.'

The treatment consisted in purgatives and clysters, liquid diet (solid food disagreeing), and local com-

pression of the pulsating spot, by the pad of a truss, retained *in situ* by straps, &c. By February 16 he was so much better as to leave the hospital. On March 4 he was re-admitted, with exacerbation of the symptoms, becoming faint if he only turned his head to the right in bed. Three leeches behind the ear relieved this. In spite of his anæmia, he had almost certainly had cerebral hæmorrhage. A dose, containing ten drops each of tincture of digitalis, cherry laurel water, and Haller's acid elixir, was given frequently when he felt faint. On recovering himself, he asserted that just before March 4 something gave way inside, in a direction from the heart to the lower belly, and that he now had a rupture on the right side, and was therefore obliged to wear a double truss. [It appeared that he had been quacked by a peasant-woman, who had prescribed 'rupture-wort' (*Herniaria glabra*) for him.] On March 6, the roaring in the right side of the head was much better. On the 7th and 8th, the pulsation in the umbilical region was less. On the 9th, the bellows-murmur was less clear and lower-pitched. All this time he complained of tremblings and 'titterings' in the extremities. On March 12, he only complained of a roaring noise in the left half of his head. The former treatment, as to diet, moderate compression over the tumour, &c., was carried out all the time; and on April 3 he considered himself cured, and left the wards to go to his own home.

In commenting on this case, Dr. Kulischer remarks that his colleagues verified the physical signs, and that all the symptoms correspond with those described by Lebert and Virchow. He thinks Wilson's case of aneurism of the superior mesenteric artery, quoted by Lebert (*Krankheiten der Blut- und Lymphgefäße*, pp. 15-33), most parallel, because the celiac axis, splenic, and inferior mesenteric might be fairly excluded; but he will not decide whether the trunk of the aorta, the superior mesenteric artery, or one of its branches, such as the ileo-jejunal, was the seat of aneurism. Some of the symptoms corresponded to aneurism of the aortic trunk. It is, however, possible that the horizontal part of the inferior pancreatico-duodenalis artery was compressed by an aneurism of the superior mesenteric at the part where this vessel passes between the pancreas and the duodenum. This might explain his emaciation and constipation, and his feelings of a solid body moving about. But the latter might also be explained by the dilatation of an artery (perhaps one of the ileo-jejunals) in the mesentery of the patient. The queer feelings (*Wallungserscheinungen*) which sometimes occurred spontaneously, and were sometimes artificially induced, may have been due to hyperæmia of the brain, or perhaps to an opposite condition of anæmia. On March 4, it is probable that there was capillary extravasation within the cranium, chiefly on the left side. It may be, that some aneurismal dilatation of the cerebral vessels may explain the previous symptoms. As regards the prognosis, though Lebert and others recite numerous cases of cure, the emaciation of the patient, and his careless habits, lead one to fear the worst for him. He will very likely resort to a peasant-woman again for advice. Sestier (quoted by Lebert, l.c. p. 33, from the *Bulletins de la Société Anatom.* vol. viii.) gives a case in which an aneurism of a branch of the hepatic artery proved fatal, not by bursting or hæmorrhage, but merely by causing emaciation. Dr. Kulischer hopes to hear of the further progress of this case; one of his objects in recording it being to call

the attention of those medical men into whose hands Chapugin may come to the early history of the case.

[The reporter regrets the omission of two or three points in this excellent clinical history. The first is, that lateral expansion of the tumour, though hinted at, is not clearly expressed; a second, that the details as to the tumour itself are very scanty; and the third, that no sphygmographic tracings appear to have been taken from the femorals or any other artery. Cases of 'pulsatile aorta' with great emaciation, due to obstinate constipation, which resemble the recorded case in many particulars, are not very uncommon in large hospitals.—*Rep.*]

W. BATHURST WOODMAN, M.D.

SURGERY.

GOSSELIN ON RUPTURE OF THE TENDON OF THE TRICEPS CRURALIS.—A patient, aged sixty-two, suffering from slight locomotor ataxy, had above the left patella a great gap. On putting the fingers into this gap, the superior border of the patella could be hooked up and the posterior surface of the bone felt. The patient stated that it was due to a fall four months before, and was followed by considerable swelling. He fell backwards and pulled a piece of furniture on to the part injured. Treatment was inefficacious. M. Gosselin draws attention to two important and instructive points, viz.: 1. The non-consolidation; 2. The treatment to follow in similar cases. 1. Consolidation in these cases is a rare event. M. Demarquay thoroughly treated this question in 1863, and has collected twenty-two cases. This accident is not extremely rare, and the scattered observations have been collected and published in the *Gazette Médicale* by M. Demarquay. Among these he found that there were some who rapidly became cured—after twenty or thirty days—and others were not benefited. In proceeding to inquire into the cause of this non-union, M. Gosselin admits that the explanation is not easy, seeing that tendons unite usually in other situations. Nélaton, in his *Éléments de Pathologie Chirurgicale*, insinuates that the want of success is due to inappropriate treatment, i.e. that the limb has not been rendered sufficiently immovable, and he attaches great importance to the dextrine bandage. M. Gosselin does not agree with this view, but believes that there are other conditions, such as idiosyncrasies, superadded to the treatment, which cause this unsatisfactory state of things. In the present case, M. Gosselin thinks that there was rupture of the synovial membrane of the joint as well—a rare condition, and one which he has seen a very few times.

2. In ordinary cases, the success of the treatment depends much on the position of the limb, its immobility, and the application of a proper bandage. The limb should be placed on an inclined plane, the foot much raised, and, so that the immobility may be quite complete, a posterior splint must be applied, then, over all, an immovable bandage.

H. A. REEVES.

BROCA ON DISLOCATION OF THE TIBIALIS POSTICUS MUSCLE.—M. Broca reported to the Academy of Medicine on January 6, notes of a case of dislocation of the tendon of the tibialis posticus, caused by the too rapid descent of a balloon. The nature of the injury was determined by MM. Courty,

Ollier, and Pozzi. After the tendon had been replaced, a silicated bandage was applied, and twice renewed. Three months afterwards the patient, a medical man, was able to walk a little, but limped. The communication was concluded by a comparison of this case, which was described as unique, with other muscular dislocations, especially those of the peroneal muscles. M. Gosselin pointed out that it was necessary to be careful that the dislocation was thoroughly maintained in place under the silicated bandage, and added that the cure could not be complete till the tendon had contracted adhesion to its sheath.

LE FORT ON A TIBIO-CALCANEAN OSTEO-PLASTIC OPERATION.—In the *Gazette Hebdomadaire* of November 7, 1873, M. J. Le Fort describes an operation which is a modification of Pirogoff's osteo-plastic method, in which he proceeds as follows. He commences the anterior incision 2 centimètres (.8 inch) below the malleolus externus, and directs it forwards to the middle third of the os calcis. On arriving at this point, the knife describes a curve whose anterior convexity corresponds with the astragaloscaphoid articulation; as soon as the internal ligaments of the foot are reached, the knife is directed backwards, and stopped at a point 3 centimètres (1.2 inch) in front of the inner malleolus. Then lifting up the foot, he fashions a plantar flap equally convex with the dorsal, passing transversely under the sole of the foot, and meeting the external incision below the outer malleolus. Next, the dorsal flap is dissected up, in order to find the tibio-dorsal articulation, and great care is taken in isolating the flap so as not to wound the posterior tibial vessels. Dividing the ligaments attaching the foot to the fibula, the point of the knife is thrust between the os calcis and the astragalus, as in the subastragaloid amputation, and the interosseous ligaments are divided. The foot is then separated and dislocated inwards, and the posterior flap fashioned as in Chopart's amputation. In order to disengage the astragalus, it is seized with a strong pair of forceps, and all attachments to the leg are divided. It only remains then to saw the os calcis from behind forward, from which the whole superior articular surface is removed, in such a way as to extend forward close to the articulating surface with the cuboid. Afterwards, all the soft parts being isolated, the articular surface of the tibia and fibula are sawn off, and the cut surfaces of the bones placed in opposition. M. Le Fort maintains that by this method he obtains a firm and perfect basis of support, without the grave inconveniences attending Pirogoff's method.

SCHINZINGER ON THE REMOVAL OF FIXED BANDAGES.—In the *Berliner Klinische Wochenschrift*, no. 9, 1874, Dr. Schinzinger, of Freiburg, describes a method by which the different kinds of fixed bandages may be removed in the quickest and easiest manner; namely, by dividing them by means of a chain-saw, from within outwards. The skin being enveloped in a flannel bandage, or with wadding and a roller bandage, he lays an oiled ribbon or fillet, parallel with the long axis of the limb, upon the roller, and covers this fillet with a strip of blotting-paper an inch broad, allowing an inch or two of the end of it to appear above and below the bandage. After that, the materials of which the fixed bandage are to be constructed, are laid on. A few minutes after the setting of the bandage, the mobility of the guiding-band must be ascertained by pulling at it.

If the bandage have to be taken off some days or weeks afterwards, he fastens to the lower end of the tape, with a strong silk thread, a Jeffray's chain-saw, and draws it, by means of the tape, beneath the bandage from below upwards; in a few seconds, the hard material is cut through by a clean saw cut. Should the bandage be broader than the ordinary length of the saw will pass through (about 16 inches) the oiled band is made to hang out through a gap in the fixed bandage, or holes are bored in it and the fillet seized and drawn through, and thus the structure is cut through in several lengths.

By this means, Dr. Schinzingler has cut through fixed bandages made of plaster of Paris, dextrin, water-glass, and magnesia-water-glass; of these, the last offered the greatest resistance.

PEITAVY ON REDUCTION OF A DISLOCATION INTO THE FORAMEN OVALE OF SIX MONTHS' STANDING.—In the *Wiener Medizinische Wochenschrift* for November 22, 1873, Dr. L. Peitavy, of Freiburg, communicates an account of this case. A man, thirty-four years old, fell down a well thirty feet deep on August 18, 1872, and dislocated the head of the thigh-bone into the foramen ovale. On his admission to the Clinic on February 14, 1873, his condition was as follows. Whilst standing, the left thigh-bone was strongly abducted, bent, and rotated outwards. The pelvis was rotated forwards and towards the left side. There were a left-sided scoliosis of the lumbar vertebrae and a right-sided of the dorsal, and the axis of the thigh was directed inwards. When he lay down, the thigh was flexed and the inguinal fold obliterated, and on placing the leg symmetrically, the distance, measuring from the superior anterior iliac spine to the under border of the patella, was on the right side 44 centimètres (17½ inches), and on the left 41 centimètres (16 inches). On resting on the lumbar vertebrae, the angle of flexion of the thigh was 111° to the bed, the angle of abduction 35°, and the rotation external; the inner malleoli could only be approximated 8½ inches. In this position the distance from the symphysis pubis to the sole, was on the left side 81 centimètres (nearly 32 inches), on the right 75 centimètres (29½ inches). Adduction was arrested, abduction slight, flexion possible.

The dislocation was at last reduced under chloroform (the flexion method having failed a week beforehand), by laying the patient on a table, fixing the pelvis with a cloth, and obtaining counter-extension by means of a perineal band. The extension was made by two students from nooses placed round the thigh above the knee, whilst Professor Czerny took charge of the direction of the thigh, and, at the moment the extension was applied, he rotated the thigh inwards and adducted it. After two attempts in this manner, the head of the bone was replaced in the acetabulum. There was no sign of fracture, and very slight reaction. Ice-bags were applied, and a little later the constant current was used.

The patient was unable to walk on his discharge, four months after, without a stick, owing to palsy of the glutæi and flexors of the thigh, arising from pressure on the nerves.

EDWARD BELLAMY.

GOODWIN ON THE USE OF THE SOLAR RAY AS AN ESCHAROTIC.—Dr. R. S. Goodwin, of Thomastown, Connecticut, writes to the *Philadelphia Medical and Surgical Reporter*, of March 7, that he has for several years used the concentrated rays of the sun in the destruction of nævi, warts, and other trouble-

some superficial growths of the skin, and finds it a very convenient and efficient caustic. He has destroyed chancres with it, and finds it also an admirable method for the local treatment of syphilitic condylomatous growths. In the removal of nævoid growths from the face, he thinks no other caustic leaves so little scar. It never gives rise to hæmorrhage. The pain is not excessive, and is not prolonged after its use. Inflammatory action and suppuration have rarely followed. The eschar drops off in from four to six days after the cauterisation, leaving a surface which heals kindly and rapidly.

By a very little practice in manipulation, the solar caustic can be applied accurately to just so much of the surface as it may be desired to cauterise, and to no more. Its action, moreover, can be limited to the slightest superficial blister, or its effects can be made to penetrate to the depth of a half inch or more at one sitting.

Dr. Goodwin uses a double convex lens, about two and a half inches in diameter, and having a focal distance of nearly ten inches. This lens is mounted on a circular brass rim, having a short flat ebony handle. The patient being placed in the direct sunlight, before an open window, the 'focal point' can be directed at pleasure upon any part. The tissues are destroyed almost instantly to the depth of the skin, with a slight snapping or crackling sound. By a prolonged application, the flesh may be charred to a considerable depth. It is very interesting to see the rapid coagulation of the blood and the shrivelling of the blood-vessels in a nævus under this potent agent.

Dr. Goodwin says that he has found the solar caustic useful in repressing excessive granulations in a badly healing ulcer. He is aware that this method of cautery is not new, but it is not to any extent, at present, in general use. It seems to him, however, that it presents advantages in various superficial operations upon the skin and its morbid growths, and deserves a more general trial.

The editor of the *Reporter* remarks on this subject: 'While agreeing with our correspondent on the value of the solar cautery, we must add that great caution should be exercised in using it in destroying nævi on the face. It is by no means easy to avoid leaving a cicatrix; and the employment of it in several cases, one upon a professional gentleman, has led us to believe that the pain is severe and not of brief duration.'

MATERIA MEDICA AND THERAPEUTICS.

BATTEY ON SACCHARATED CALOMEL.—Dr. Battey (*Atlanta Medical and Surgical Journal*, August, 1873) says that certain peculiar effects follow the administration of calomel prepared in a certain manner, as follows. Six grains of calomel and twelve grains of refined cane-sugar are ground long and diligently in a mortar, until both are thoroughly combined in impalpable powder. During the trituration a delicate canary colour is developed, which is partially lost by keeping. He says that the activity of the calomel is greatly increased by this trituration. Further, chemical analysis proves that the yellow colour is not due to a conversion of the calomel into any mercurial salt soluble in water. He gives the

equivalent of one-half grain of calomel of the saccharated calomel for a dose. From cases reported, it is clear that this dose produces an active bilious purging, surprising to one accustomed to the effects of administration of ordinary calomel. The doctor offers no explanation, but says that any one can verify the fact stated. As a purgative, he gives the same dose both to children and to adults. His cases show that its action is more certain in adults than in children.

REMINGTON ON FLUID EXTRACT OF SUMACH BERRIES.—The berries of the sumach, containing a considerable quantity of malic as well as tannic acid, furnish one of the most agreeable of astringents for mouth-washes, gargles, &c. The following formula, following closely the Pharmacopœia process for astringent fluid extracts, is offered by Joseph P. Remington (*American Journal of Pharmacy*), and is said to yield an elegant preparation, of a rich red colour, representing well the virtues of the berries.

R. Sumach berries, in moderately fine powder ʒxvj
Glycerine flʒiv
Alcohol, water, of each a sufficient quantity.

Mix half a pint of alcohol, three fluid-ounces of glycerine, and five fluid-ounces of water; and, having moistened the powder with four fluid-ounces of the mixture, pack in a suitable percolator, pour on the remainder of the menstruum, close the percolator and allow the powder to macerate for four days; then open the percolator and continue the percolation till twenty-four fluid-ounces have been obtained. Of these reserve the first fourteen fluid-ounces, and evaporate the remainder to two fluid-ounces; mix with the reserved portion, and filter if necessary.

A good gargle and mouth-wash may be made as follows.

R. Fluid extract of sumach ʒiv
Potassium chlorate ʒij
Glycerine, pure ʒij
Water ʒvij
Mix and filter.

JOHANNET ON CONTINUOUS GARGLING IN CROUP.—Dr. Johannet, of Chelles, in a paper lately laid before the Academy of Medicine of Paris, treats of the efficacy of continuous gargling in cases of croup. The important point in presence of this disorder, according to Dr. Johannet, is that whatever may be the nature of the gargle chosen, it must be used without intermission. It would appear that the fauces can no longer secrete the false membrane from the moment that the liquid of the throat is changed, and the temperature lowered; just as moss cannot produce itself on a roof in the presence of unceasing rain. 'So soon,' writes Dr. Johannet, 'as I come to the bedside of a patient in whose case I find false membranes in the throat, if I find him in bed I make him get up directly, and without losing any time I force him to gargle with any liquid at hand; pure water, wine and water, cold milk; it matters not what. The essential point is that the washing out should be reiterated and incessant, and that it should be continued day and night without any intervals of sleep during thirty or forty hours; so long as the false membranes are not modified to such an extent that the danger seems to be averted. Generally I have three different glasses placed before my patient—a glass of pure water, a glass of wine and water, a third of alum water, composed of a teaspoonful of powdered alum in a glass

of water. If fever, somnolence, or cephalalgia, be present, they disappear in a few hours, with the constriction of the throat. The patient thenceforward performing deglutition easily, I induce him as much as possible to eat something, anything he likes, such as fruits in season, apples, pears, cherries, oranges; of course, if I can induce him to take more substantial food, I am delighted to give it to him. Sometimes even, in the hope of producing a useful reaction, I prescribe a solution of perchloride of iron (6 grammes to 200 grammes of water), to be taken by teaspoonfuls every hour, and to be followed immediately by a mouthful of cold milk. But there are cases when cold water, simple cold water, by incessant application, has been successful in an unhoped for degree. For instance, with young children, where gargling is impracticable, I make injections of water into the mouth by means of the ordinary syringe, either by the mouth, taking care to press on the base of the tongue; or by the nasal fossæ when the child offers too great a resistance to the opening of its mouth. At least three persons are then necessary; one holds the child's hands and feet, another fixes the head as in a vice, while the third administers the injection. In the interval of these great washings, which I cause to be performed every quarter of an hour, I take care to have water or cold milk swallowed by small spoonfuls almost incessantly. If it happen that the overfilled stomach rejects the absorbed liquid, I am glad of it; and none the less continue to have fresh ingurgitated either by small spoonfuls, or by large injections with the syringe.'

In the course of three months, M. Johannet has had the opportunity of employing this method thirty times, and, notwithstanding the serious nature of the cases, has only lost two of his patients.

ORÉ ON ANÆSTHESIA PRODUCED IN MAN BY INJECTION OF CHLORAL INTO THE VEINS.—Some time since, M. Oré expressed to the Société de Chirurgie of Paris the opinion (based on experiments with inferior animals) that chloral, injected into the veins, was a surgical anæsthetic superior to chloroform. He has now extended his observation to the human system; having lately treated a man, aged fifty-two years, brought to the Saint André Hospital at Bordeaux, who was suffering from confirmed traumatic tetanus in the masticator muscles, arising from a slight bruise on the left middle finger. He details his treatment and the symptoms observed, and the following consequences are deduced.

1. There was not the least indication of phlebitis. A small abscess only, of special form, was produced at the lower part of the right forearm (where the injection was made), owing to the penetration of chloral into the cellular tissue. 'My experiments with four animals,' M. Oré observes, 'indicate that it is always thus when the dose is large. This leads to a conclusion important for clinicians, viz., that the subcutaneous method is the most defective for administering chloral. If the quantity injected into the cellular tissue be small, it will be absorbed without producing local injuries, but also without having any effect on the system. If, on the contrary, it be large, it causes abscesses. In the former case it is useless; in the latter it is injurious.'

2. A second consequence is the absolute insensibility, rapidly produced and of long duration, when the substance is brought immediately into contact with the blood. At 5 p.m., on 9th February, M. Oré

injected twice, at intervals of three or four minutes, a solution of nine grammes of hydrate of chloral and ten grammes of water. Immediately after the second injection the patient fell into a quiet sleep, the respiration becoming calm and regular, the pulse descending from ninety to seventy, and the muscular rigidity almost wholly disappearing. The anæsthesia was most complete. M. Oré removed a nail from the patient in two pieces, without any murmur from him. At 9 p.m. the anæsthesia still continued, and M. Oré could pass his finger over the ocular conjunctiva without producing reflex action. The patient did not awake till 4 next morning. By 9 a.m., when M. Oré saw him, the sensibility had returned, but was still incomplete in the lower limbs. (Injection was repeated several times with like results, which are fully described.)

3. Hydrate of chloral, administered by the veins, rapidly masters tetanic injuries. Three injections of ten grammes, repeated during three days, at intervals of twenty-four hours, caused (along with sleep) complete paralysis of sensibility and of motility. M. Oré insists particularly on the *small quantity* required to produce a favourable result. By the direct penetration of chloral into the vessels, the physiological action of the substance is as if decupled. What is required to cure tetanus (the author points out), is not to maintain the patient in narcosis during twenty-five hours, but to bring the too exalted reflex power of the spine to its physiological state, and thus to hinder the muscular contraction from becoming general. It is this that chloral does, but only if administered by the venous method.

ALEX. B. MACDOWALL.

PUBLIC HEALTH.

CAMERON AND ANGUS SMITH ON THE INFLUENCE OF CHEMICAL VAPOURS ON AGRICULTURAL PRODUCTS.—At a meeting of the members of the Lancashire Chamber of Agriculture, held at the Town Hall, Newton-le-Willows, an address was delivered by Dr. Charles A. Cameron, analyst to the City of Dublin and the Royal Agricultural Society of Ireland, on 'The Influence of Exhalations from Manufactories on Agricultural Products.' The chair was taken by Sir Robert T. Gerard, Bart.

Dr. Cameron said he must in the first place express his thanks for the compliment which the Lancashire Chamber of Agriculture had paid him, in inviting him from the other side of the Channel to give a lecture on the nature of the gases which were evolved in such large quantities from some of the manufactories of this country, and to state what he had seen with regard to the evil effects of those gases upon the agricultural products of the different districts in which certain works were situated. He came there as an unprejudiced person, having no leaning on the one side towards the manufacturers who produced the gases, nor on the other hand towards the agricultural persons who were affected by those gases. It would be necessary to describe the different gases, vapours, and solid particles evolved from the multitudinous works and manufactories which were scattered broadcast over Lancashire. In making salt-cake, a large quantity of gas called muriatic acid was produced. Most of this gas was formerly allowed to escape into the atmosphere, as it was incidentally produced in larger quantities than it

could be utilised; but in 1862 an Act of Parliament was passed, which prohibited manufacturers from permitting more than five per cent. of the gas produced in their works to escape into the air. Dr. Angus Smith was appointed chief inspector, to see that the provisions of the act were carried out. From his reports, it appeared that in many works the escape of the acid gas was almost completely prevented, whilst in others the amount escaping occasionally was considerably over five per cent. The Alkali Nuisance Prevention Act had proved of great value, but it did not wholly abate the evil; as, owing to the recent great increase in the number of alkali works, and to the occasional extensive leakages of gas from a large proportion of them, the quantity of muriatic acid evolved into the atmosphere was injuriously large, and caused considerable damage to agricultural products. The alkali-works were not, however, to blame for all the mischief done to the flora of Lancashire. From the oil of vitriol works, which included the artificial manure manufactories, sulphurous and nitric acids were evolved; from the copper smelting works, sulphuric acid; and sulphurous acid was evolved from the salt cake, or sulphate of soda, largely used by the glass bottle makers. From the gas works, soap and caustic soda works, the poisonous sulphuretted hydrogen gas was evolved in dangerous proportions. The alkali makers generally prepared bleaching powder, in producing which chlorine—a far more poisonous gas than muriatic acid—was evolved into the air. The lecturer prepared the gases to which he referred, and exhibited the effects. He next referred particularly to the special injury which these gases inflicted on the trees, hedges, and crops of Lancashire; and described what he himself observed in a tour through the manufacturing districts. In many parts he found the trees and hedges utterly destroyed. On the farm of Mr. Davenport, of Dutton, he saw a crop of wheat, the produce of six acres, so much injured by the exhalations of a cluster of chemical works that it was not worth thrashing. On the farm where the crop was produced every vegetable bore the marks of the acid, and on some of them it could be distinctly tasted. A plantation of willows close to the works was utterly burnt up. All this damage was done within two years, the period of the existence of the works. Some gases travelled two or three miles without being condensed, or were sufficiently mixed with the air to be unrecognisable. The exhalations from a cluster of works could do heavy damage at a mile distance. Black smoke was also injurious to agricultural products. The acid gases did most mischief in wet weather. The hazel, oak, beech, and birch were most affected by the gases; next, the sycamore and maple, spruce, willow, hawthorn, ash, and lime; and amongst the least susceptible were the poplar, aspen, and elder. Fruit trees resisted better than most forest trees.

Dr. Cameron said that the most fashionable part of Dublin was subjected to the same nuisance, and property had been very much depreciated in value in consequence. Everything that was possible had been done to abate the nuisance. In the case of works which emitted sulphuretted hydrogen gas, they had succeeded to a great extent, but there was no constant supervision. What he suggested was, that the works should be put under a scientific inspector, the same as alkali works.

Dr. Angus Smith said that there were a few points upon which he might express an opinion in somewhat different language to Dr. Cameron, but upon

the whole he had given a very full and true account of the state of matters which existed in Lancashire. It could not be doubted for a moment that the gases from the manufactories at St. Helen's and Widnes did a great deal of harm to vegetation. It was apparent to every one, even when passing rapidly through the county in a train. The best mode of dealing with the question required a good deal of consideration. The gases might be divided into two kinds—the avoidable and unavoidable; that was to say, those which could be dealt with and those which could not be dealt with. For example, the sulphurous acid from the collieries, and from coal smoke generally, was a substance they could scarcely attempt to treat otherwise than now. He thought it must be allowed full freedom, at least for a long time to come; and he did not see any method of diminishing the nuisance, except by diminishing the combustion of coal, and that of itself was a very large question. That gas, no doubt, did some injury to the county, especially in the south portion, and the trees bore abundant evidence of the deleterious action of coal smoke. But, then, there were other gases, which came from the so-called chemical works, such as Dr. Cameron had been speaking of—muriatic acid, sulphuric acid, and sulphurous acid. These did direct and certain injury within a radius of one, two, three, or four miles, according to the quantity evolved in the district. He might repeat what Dr. Cameron had said—namely, that the means of condensation of these gases were not keeping pace with the enlargement and increase of these manufactories. A large work might only give out five per cent. of muriatic acid gas; and although that quantity might seem small, it might prove in reality very large. A small work giving out twenty per cent. might, in reality, do much less damage than a large work which evolved only five per cent. The question was, therefore, a very complicated one. He could not pretend to deal with the subject in a short speech; but he would repeat the opinion he had given in his published reports, that the time had come when a little more pressure should be put upon the manufacturers of chemical substances in all those cases where noxious gases were evolved in the process. As to the division of the county into manufacturing and non-manufacturing districts, that was an idea he entertained at one time, and it was carried out in Belgium; but there were many difficulties in the way of putting it into operation in this country. As to the second part of Dr. Cameron's proposal—the distribution of damages according to the amount of gases evolved by each manufacturer, he did not think there were any insuperable difficulties in the way of carrying out that part of the scheme, and it might be useful in considering the subject anew. However, without being definite upon any of these points, he was quite definite upon this point—that more legislation and a little more pressure ought to be put upon chemical manufacturers, at the same time always remembering that pressure must be such as not to destroy a very important industry, and that both agriculturists and manufacturers should have full and fair consideration in the adjustment of their rights.

Mr. H. Neild said the subject was a very large one, as affecting both the commercial and the manufacturing interests of the country, and they had better not commit themselves to propounding any specific remedy. The amount of damage which was being done to agricultural property in this part of the

county by the chemical vapours was patent to every person who travelled on the railway.

WHITMORE ON ANALYSIS OF ARTICLES OF FOOD AND DRINK.—Dr. Whitmore has presented to the Vestry of St. Marylebone his fourth Quarterly Report of his analyses of various articles of food and drink purchased by the inspectors and other persons in the parish.

The samples analysed were 62 in number, and consisted of milk, tea, coffee, cocoa, chicory, sugar, black and white pepper, mustard, arrowroot, flour, butter, lard, vinegar, and ale.

The milk—of which there were 21 samples—varied greatly in specific gravity, richness in cream, and in the amount of other constituents; but inasmuch as, with three exceptions only, all the samples contained as large a quantity of these constituents as is sometimes found in poor milk, known to be genuine, he could not certify that either of them had been adulterated. With regard to the excepted samples he found, after taking as a standard of comparison the very poorest genuine milk, that they were diluted with from 10 to 12 per cent. of water, and that from one of them a considerable quantity of cream had also been abstracted. In all these cases the vendors were prosecuted, convicted, and fined.

All the samples of tea were genuine, but the leaves were much broken, and in some of the samples a considerable quantity of tea-stalks and dust were found.

Five samples of coffee were examined; of these three were free from adulteration, and two contained a large quantity of chicory. One of these latter was wrapped in a paper, on which it was stated to be a mixture of coffee and chicory. With the other sample there was no such announcement; it was sold as coffee; and a summons will probably be taken out against the vendor of it.

The samples of cocoa were sold as 'prepared cocoa,' and consisted of a mixture of cocoa, sugar, arrowroot, or sago-starch.

All the samples of sugar, pepper, and chicory, appeared to be genuine.

Four samples of mustard were analysed; two were genuine, and two adulterated with wheaten flour and turmeric. In one of these latter cases the vendor should be prosecuted, as it was sold as genuine mustard.

The samples of arrowroot appeared to be genuine St. Vincent arrowroot; no potato or other starch granules could be detected in either of them.

Six samples of vinegar were analysed; they were all specimens of malt vinegar, and were free from any other adulteration than that of sulphuric acid. This acid is, however, he believes, permitted by law to be added to vinegar to the extent of about one part of the acid to one thousand parts of vinegar. In these samples the quantities varied from 0.213 to 1.421 parts of sulphuric acid in 1,000 parts of vinegar.

The samples of butter were carefully analysed, and the only adulterative ingredients found in them were water and salt. In one sample the water amounted to 13 per cent., and the salt to 6 per cent.; in a second the water and salt were respectively 13 and 5 per cent.; and in a third 16½ and 3 per cent. None of these quantities can be considered excessive, and, in his opinion, do not constitute adulterations.

The samples of lard were all genuine; the quantity of water found in them varied from 3 to 8 per cent. only.

In the one sample of ale analysed, no injurious or unwholesome adulteration was detected; it had simply turned sour.

Three samples of flour were brought to the inspector by an inhabitant of the parish to be analysed. One was genuine, the second contained a large quantity of alum, and the third an excessive quantity of the same salt. Dr. Whitmore has reason to believe that the two samples had been purposely adulterated in order to test his ability to detect the presence of alum in flour; and, as he has since heard nothing of the person who brought the samples, he supposes that the certificate which he gave of the results of his analyses was correct.

A COLLIERY DISTRICT.—Mr. Edward Robson, the inspector of nuisances for the Bedlingtonshire Local Board District, has brought under the notice of the local board the discreditable sanitary condition of several of the colliery districts. He says that in the North Blyth and Link End district, which is almost entirely the property of Sir M. W. Ridley, Bart., there are 41 houses, cottages, and tenements, two being public-houses, with a population of nearly 200, and the whole are without privy, ash-pit, or sewage accommodation, and are, in consequence, in a most deplorable state. At North Blyth the ash-heaps form high mounds, being an accumulation of years past, the non-removal of which, it is supposed, sent the cholera through the district twenty-two years ago. At Scotland Gate, the filthy and unsanitary state of the place called Colliery Side is almost indescribable. The great cause of this is over-crowding; into every kitchen, room, garret, and stable are large families crammed, without any additional conveniences having been added to the property. It is therefore not to be wondered at that death and disease are never from the doors. At the Bedlington Colliery 76 houses, with nearly 500 inhabitants, are still without privies and sewerage. The water is principally supplied from carts, at $\frac{1}{2}$ d. per pail. At Bedlington Station there are 120 houses or tenements, with an overflowing population of 752. There are only 60 privies and 30 ash-pits, little or no sewerage, no water supply, every house crammed from kitchen to garret—in many are six adults and from five to seven children, with only a small room and loft to stow this human cargo. The highway leading to Cambois bears abundant evidence of the degraded state of this place, through the want of more necessary accommodation and a proper sewerage arrangement. At the Iron Works there is not a single ash-pit or privy for the overcrowded tenemented property. Every conceivable filth is deposited in all the holes and corners. After a shower, or in the heat of the sun, the stink is abominable. At the Nedderton Colliery there are 146 single and double houses, destitute of all sanitary arrangements, and containing a population of nearly 900, old and young. In many instances, with no fewer than thirteen or fourteen in family, a small house of kitchen and loft is the only accommodation. The rows that are lately built, and those that are in process of building, combine everything requisite for health and comfort.—After referring to other localities in the district, Mr. Robson says: There is scarcely a part of the district which is not overflowing with sanitary defects. The majority of small houses and cottages, which exist in this as in many other parts of Northumberland, are deficient in almost every requisite that should constitute a home for a Christian family

in a civilised community. Unfortunately, whilst all are ready to admit the desirability of immediate sanitary improvements in this populous district, many are very averse to pay for them. The most important and principal requirements are—first, the immediate removal of organic matter from all places where, by putrefaction, it can contaminate the air, food, and water; secondly, sufficient of breathing space allowed for each inhabitant; and thirdly, a plentiful supply of pure water. One special exception is made by Mr. Robson in the case of the Cambois Colliery. There, he says, everything has been done for the comfort and sanitary condition of the miners that a rich company and a liberal-minded man could devise. The houses are large and airy, privies clean, and ash-pits spacious. The drainage is excellent, every house having a patent sink and trap. Water is supplied to large tanks from a well—it is plentiful, and of good quality if properly filtered.

EXPENSES OF PORT SANITARY AUTHORITIES.—At the recent meeting of the Associated Chambers of Commerce, one of the subjects discussed was the charges cast upon the Port Sanitary Authorities in carrying into effect the regulations issued by the Local Government Board with reference to cholera; and a resolution was passed by thirty-six votes against nine to the effect that the charges incurred by the Port Sanitary Authorities for the prevention of the introduction of cholera and other infectious diseases from infected ports into this country should be payable out of the Consolidated Fund. In the course of the discussion, it was urged, that the expenses which are incurred at the different ports for preventing the importation of disease are not merely for the benefit of the towns on the sea border, but for the country generally; and that it is hardly equitable, therefore, that the expenses should fall exclusively on the areas abutting on the ports. The Government already, under the Quarantine Acts, bear the costs incurred in protecting the country against yellow fever.

AMENDMENT OF THE SANITARY ACTS.—The Health Committee of the Sunderland Town Council have passed the following resolutions as to amendments of the Sanitary Acts. 1. **Water-Supply.**—Provision should be made, as proposed in the bill submitted by Sir C. Adderley last year, that any inhabited house without an adequate supply of wholesome water for domestic purposes should be deemed a nuisance within the Nuisance Removals Acts. 2. **Buildings, foundations, damp, &c.**—Power is urgently wanted to secure that inhabited houses shall be built on proper, dry, and wholesome foundations. Frequently, in Sunderland and other large towns, vales, quarry, and other holes are filled up with rubbish and filth, often of the most objectionable kind, and after a short time built upon, and no power is vested in the sanitary authority to prevent it. Power should also be given to require spouting for inhabited houses, not simply as now, where the drip would be upon the public footpath, but in all cases where necessary to secure freedom from damp. 3. **Drains.**—The sanitary authorities should be enabled to lay the house-drains in cases of new houses, and charge cost to the owners. 4. **The registrars of births and deaths** should be bound to furnish immediate notice to the medical officer of health of any death occurring in the district from any infectious disease, and weekly returns of all deaths, to be paid at the same rate

as for returns under the Vaccination Acts; and all medical practitioners, in any hospital or establishment which receives money from the rates or taxes, should be compelled to furnish returns of sickness from infectious diseases, specifying the neighbourhood where such cases have arisen.

PORT SANITARY AUTHORITY OF LONDON.—The medical officer of health for the port of London, Mr. Leach, has, the *Times* says, recently issued a sanitary report, which contains not only a statement of the work done within his district, but also some account of its peculiar features, and of the general principles on which the sanitary inspection and supervision of ports should be conducted. The sanitary jurisdiction of the port of London extends from Teddington Lock to the North Foreland, and is 88 miles in length. It includes eight sets of docks and 13 creeks, and is in contact, at high water mark, with the districts of 46 different sanitary authorities, all of whom had riparian powers before the Public Health Act of 1872 came into operation. More than two-thirds of the work of the sanitary officers of the port is, however, confined within the ten miles lying between London Bridge and Woolwich Arsenal Pier. The ten miles first referred to contain an average of 400 moored vessels, of which more than 90 per cent. have crews on board. A large proportion of these vessels require constant general inspection; and many of the old class of coasters, which do not come under the cognisance of the officers of Customs, are said to be in especial need of supervision. In little more than three months the sanitary inspector visited and inspected 505 vessels of all kinds in the river, attention being particularly directed to those which came from ports infected with, or suspected of cholera. Mr. Leach considers that, with the aid of a steam launch, an active officer may inspect 60 vessels a day in the river, and 60 or 70 in the docks. The latter contain an average of from 600 to 700 vessels, 50 per cent. of which have crews on board; and out of 1,494 of these vessels that were inspected, the sanitary arrangements of 338 were found to be more or less defective. The creeks, also, seem to require especial vigilance; they being mostly occupied by barges containing offensive cargoes of various kinds, such as manure, street sweepings, gas liquor, bones, and other noxious substances. The materials of these cargoes are stored in depôts on shore, the condition of which is, in many cases, such as to call for the active co-operation of the shore authority. The most important part of Mr. Leach's duties during the half-year arose out of the action rendered necessary by an importation of cholera. On July 27 the steamer *Iris* arrived in the port from Hamburg, bringing 82 Danish and Swedish emigrants from Kiel, Hamburg, and Copenhagen. These people were landed at Blackwall, and were sent to various lodging-houses in Whitechapel until they could re-embark to proceed to New Zealand. A few hours after the landing, two of their number were attacked by cholera, and one of them speedily died. Mr. Leach arranged with the harbour master of the port for the isolation and fumigation of the *Iris*, and the medical department of the Local Government Board took measures to prevent the immediate departure of the emigrants; and strongly recommended that they should be removed from the metropolis and isolated for the purposes of observation. After careful consideration, the emigrants were collected and conveyed to the

hospital ship *Rhin*; and eventually, after some of them had recovered from attacks of choleraic diarrhoea, they were all dispatched in good health to their destination. There can be little doubt that these timely precautions preserved the east end of London from an outbreak of disease that might easily have assumed very formidable proportions. In two other cases in which cholera was brought into the port the necessary protective measures were immediately adopted. Mr. Leach describes at length the hospital ship *Rhin*, which he considers unsuitable in many respects for the purposes for which she is required. He suggests that a gun-boat or a small vessel of 80 or 100 tons, to contain 16 or 20 patients, would meet all the necessities of the case. He points out his own need of a steam launch, without which it is impossible for him to carry on the duties committed to him; and he concludes a very clear and interesting report by a statement of the qualifications and duties of a port medical officer and of his sanitary inspectors.

OPHTHALMOLOGY AND OTOLOGY.

WECKER ON CYSTOID DEGENERATION OF THE IRIS.—M. Wecker (*Annales d'Oculistique*, July and August, 1873) believes that quite apart from the cases of extreme anterior or posterior synechia which cause cystoid degeneration of the iris, any folding of the iris, such as occurs in partial or complete luxation of the lens, may do so. He records in this paper several instances of its occurrence.

Case I. A man, aged thirty, four weeks previously had received a severe blow upon the right eye from the branch of a tree; there was no wound of the eye but absolute blindness and excessive tenderness to the touch. The crystalline lens was dislocated into the vitreous humour, but its exact position could not be determined. The iris was tremulous, of a greenish hue, and appeared to be drawn backwards. In six weeks all symptoms of irritation had disappeared, and the man left the hospital. In six months time he again presented himself. The front of the globe appeared curiously pointed, the cornea retained its transparency, and behind it there appeared five greyish transparent vesicles, separated from each other by deep furrows, three of them as large as peas, the others no larger than millet-seeds. In the centre, in the situation of the pupil, was a greyish opaque mass of tissue—by oblique light it could be seen that the contents of the vesicles were transparent. M. Wecker considers that the retraction of the vitreous humour, altered in its structure, had encouraged a folding backwards of the iris, and the subsequent agglutination of its surfaces to each other, and asks in what does such a case differ from those known as cysts of the iris.

Case II. At the time of siege of Paris, a woman, aged twenty, presented herself, who on the preceding day had received a blow from a spent bullet on the left lower eyelid. There was no wound of the eyelid or eyeball, but the latter had lost all perception of light, was very painful and much injected; blood in the anterior chamber prevented any examination of its interior. The removal of this by absorption at the end of three weeks made it evident that, as in the previous case, the crystalline had been displaced into the vitreous humour, and the iris was tremulous and drawn backwards. Some months later the eye had

become somewhat atrophied and was no longer irritable; the front of the eye was somewhat pointed, the cornea was transparent, and the iris presented the appearance of being converted into four vesicles as large as a pea, similar in every way to those previously described.

Case III. A man had received a blow on the left eye with a fist. For some weeks the eye remained blind and painful. At the end of two months the pupillary space had become clear, and showed a dislocation of the lens into the vitreous humour; the iris was tremulous and much torn.

Eight months afterwards the eye had undergone the same partial atrophy and change in shape before mentioned. There were five grey and transparent vesicles developed in the iris, three of them as large as peas and filling the anterior chamber. The eye being perfectly quiet, no treatment was adopted.

From these observations it is clear that as a result of a folding of the borders of the iris and the subsequent agglutination of these folds, diverticula are formed, which, by becoming distended, may give rise to the condition of cystic degeneration.

In conclusion, M. Wecker believes that iris-cysts may develop:

1. As a consequence of the iris becoming entangled in a wound of the cornea, the aqueous humour being retained.

2. As a result of the formation of posterior synchia.

3. In consequence of being drawn backwards and thrown into folds, the entire iris may undergo this kind of degeneration. BOWATER J. VERNON.

MISCELLANY.

CHOLERA.—A recent report from Breslau states that cholera is spreading in some parts of Upper Silesia; viz., in Lipine, Piosniki, and Schwientochlowitz. In the latter place, a number of cases occurred two or three weeks ago, of which two-thirds were fatal. The schools were closed, to prevent the further spread of the contagion.

BIRTHS AND DEATHS IN BERLIN.—In the year 1873, 36,281 children (18,660 males, and 17,621 females), were born in Berlin. Of these, 5,352 were illegitimate. There were 420 cases of twins, and 6 of triplets. The number of deaths was 28,078, including 1,562 still-births; including the latter, the deaths in the first year of life were 12,699. Compared with 1872, the year 1873 had 578 more births, and 113 fewer deaths.

PROFESSOR HYRTL.—On the 16th instant, Professor Hyrtl retired from the chair of Anatomy in the University of Vienna. At the close of his lecture, he was met by a large body of students, of whom he took a friendly farewell. An address was presented to him by the *Doctores-Collegium*, and it is intended to place a marble bust of him in the building. In the evening, there was a festival of the students, during which a portrait of Hyrtl was unveiled.

THE DWELLINGS OF THE POOR.—Dr. Whitmore, the medical officer of health for St. Marylebone, in his monthly report as to the sanitary condition of that district, remarks: 'The great and growing necessity for improvement among the dwellings of the poor and industrial classes, not only in this parish, but throughout the metropolis generally, becomes every now and then strikingly manifest. My attention has lately been called to the condition of certain tenements in Marylebone Lane. One of these

contains nineteen rooms, which would appear to have been originally constructed with most especial disregard to order in arrangement, uniformity, or convenience. Every part of this most miserable abode is in a ruinous and dilapidated condition; the flooring of the rooms and staircases is worn into holes and broken away, the plaster is crumbling from the walls, the roofs let in the wind and the rain, and the drains are very defective, and the general aspect of the place is one of extreme wretchedness. The number of persons living in this house is forty-seven. My first impulse was to declare the house unfit for human habitation, and, by means of a magistrate's order, to remove the inmates at once. A moment's reflection, however, convinced me that by adopting that course I should really accomplish no good object, inasmuch as the poor people, thus suddenly ejected, would be compelled to seek shelter in dwellings probably more crowded, and in an equally bad sanitary condition. The utmost amount of sanitary work the vestry has power to enforce has, of course, been ordered, and when completed may be productive of some little benefit to the comfort and convenience of the poor tenants and their families; but no amount of work short of entire reconstruction can render it, in the proper acceptance of the word, a healthy dwelling.'

THE ATMOSPHERE OF PARLIAMENT.—We are glad to be able to state that, during the present session of Parliament, special means are likely to be taken which will make the atmosphere of the Houses physically as well as politically clear. The ventilating arrangements of the Houses—although not equal to the difficult task of satisfying the idiosyncratic tastes of a great collection of gentlemen of all ages, constitutions, and habits of life—are singularly perfect. More air can be passed through the House without draughts, than through any similar building in Europe; the whole atmosphere of the House can be renewed in little more than ten minutes, and more air passes through the House when the windows are shut than when they are open: although such is the force of habit, that members sometimes insist in hot weather on having the windows opened, and profess themselves sensibly cooler, notwithstanding that the thermometers throughout the House immediately rise one or two degrees. Such is the force of imagination, even over the minds of statesmen, and such the power of mind over matter. During the vacation, Dr. Percy, F.R.S., to whom the control of the warming and ventilation of the Houses of Parliament has for some years been entrusted, has been trying some experiments with 'cotton-wool filters' through which all the air entering the house has been driven; the result has been such as would be startling to any one who has not been accustomed to consider the floating dirt with which the London atmosphere is loaded. The late Mr. Appold, F.R.S., the ingenious contriver of the Appold centrifugal pump, and of a great many other ingenious and important contrivances, possessed a house which was a very wonderland of curiously useful and convenient devices. The doors opened automatically, the temperature was self-regulating, and could be set for the day, or altered at any time, by setting a thermal dial. But the crowning feature of interest was a visit to the lower regions of the house, where the air was passed in for ventilation of the rooms. It was driven by fans through a succession of very fine wire sieves, and at the foot of these sieves was deposited a heap of black dust, the winnowed impurities of the air, which taught the observer a fearful lesson as to the many pecks of dust which all Londoners must annually, if not monthly, pass into their organism, and explained why it is so difficult to keep a London house clean. An inspection of the fleeces of Dr. Percy's air-filters will teach a similar lesson. Once snowy white, they are now of a heavy murky brown, thick with dust, and infiltrated with organic impurities. The experiment was tried during a heavy London fog; and there can be no doubt of the advisability of employing for the ventilation of the house an expedient which will at once purify and clear its atmosphere.

MAINTENANCE OF PAUPER LUNATICS.—Dr. Williams, Medical Superintendent of Hayward's Heath Lunatic Asylum, has published a tabulated return of the maintenance rate for pauper lunatics in all the county asylums in England and Wales for 1872 and 1873. The return shows that the average weekly maintenance rate in 1873 in the forty-five asylums was 10s. 3^d. The average weekly maintenance rate for the Sussex Asylum at Hayward's Heath was 9s. 6^d., being 8^d. less. There were only six asylums, including the Sussex Asylum, in which the rate was lower in 1873 than in 1872—in the majority the increase was very considerable.

ELECTRO-CHEMICAL BATHS.—The therapeutic uses of the electric bath have as yet been very imperfectly investigated. That it is a potent therapeutical agent can hardly be doubted; but it is not always at hand, and has been little tried. At Guy's Hospital an electrical bath has, we believe, been fitted; but, for practitioners desirous of investigating this mode of applying generalised electricity to the surface of the body, no conveniences exist. The baths hitherto known as Dr. Caplin's have been open to the objection of being under the control of an individual; they are now taken over by a company, and we are assured that every facility will be given to practitioners for conducting the treatment of their patients under their own immediate control and supervision. We hope that the results may prove to be interesting to science, and useful in practice.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, APRIL 1, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

WILKS ON THE PHYSICAL EXAMINATION OF THE CHEST.

The following instructions for examining the chest are taken from a lecture by Dr. Wilks, published in *Guy's Hospital Gazette* for February 28, and March 7.

Form.—You first of all expose the patient's chest, and look at its form. This may at once give you some information as to the general structure of his figure and temperament. Any alteration of the shape of the chest has usually existed from childhood, and may be inherited, but it is seldom congenital. The causes instrumental in producing the change of shape may be accidental, but many of these causes, being dependent on the constitution of the parents, may be regarded as indicative of a particular temperament. Abnormal chests may be unusually large or small. The former are usually acquired at a later period of life, the latter in infancy. At birth the chest is usually well-formed, and its circumference nearly circular; and it is afterwards that alterations take place in its shape. The changes depend mainly upon the state of the lung within, and also upon the condition of the bones. Anything which prevents due expansion of the lung necessarily shows its effects on the case which holds them. Any inherent weakness on the part of the infant, or acquired debility from want of food, might prevent a proper inflation of the lung, or, if once inflated, might cause a return to the fetal state or an 'atelectasis' of parts of them. A bronchitis, by causing closure of the tubes, might necessitate a collapse of the lower lobes, and thus bring about a non-expansion of the chest.

You can see how, from a want of vigorous inflation, a chest might remain in a contracted condition, and become permanently a long and narrow chest. You can also see how, from a bronchitis and want of due inflation of the lower lobes, the sides of the chest might fall in, and thus would be produced a form of thorax hollowed out at the sides which is by no means uncommon. If this condition were still further exaggerated, the lower part of the sternum would project, and a modification of the pigeon-breast would be formed. The true pigeon-breast would not be produced, I believe, unless the bones were at the same time soft; and thus the condition not only shows that during infancy there had been a deficiency in the expansive power of the lung, but the patient was the subject of rickets. In rickets the bones are soft, containing less earthy matter than they should, and show instead a red gelatinous material; you will thus observe that, when a rickety child is put on the ground, the tibiae bend forwards, the femora outwards, and the rami of the os pubis are forced inwards to produce the rostrated pelvis.

Before these deformities occur, you may sometimes see the chest flattened by pressure against the mother during nursing; and subsequently, if the soft state of the bones continue, and anything interfere with the due expansion of the lung, the chest falls in on both sides, and the cartilages thrust out the sternum in front like the breast of a bird. At the same time, the ribs become bent almost at right angles. This rickety chest is no part, as far as I am aware, of the tuberculous diathesis, and therefore you must not say, when examining the narrow pigeon-breast of an adult, that he is prone to consumption. It may be that a narrow chest shows an inherited weakness of constitution, as well as that chest which is flattened at the sides, but neither of these I should regard as the form of chest mostly met with in consumptive persons. Remember, in the first place, that subjects of tuberculous temperaments are well grown and well formed people, having the limbs straight and the head and chest large. If there be any peculiarity about the phthisical or tuberculous chest it is that it is flattened in front; that is, broad from side to side, and narrow from before to behind; thus contrasting with the barrel-shaped chest, of bronchitis. Not only is it flattened, but the sternum, instead of having any tendency to project, falls in slightly, and thus is seen to be depressed below the ribs. Whether this is a formation inherited from birth, or acquired during infancy, I cannot say, but I strongly suspect the latter. I will, therefore, ask you to remember this form, and also the narrow chest and the modified pigeon-breast having their origin in the causes named, in all of which a phthisical condition may be subsequently developed; then, also, the rickety or pigeon-breast due for the most part to the state of the bones.

A large chest, or one larger than natural, is acquired at a much later period of life, and is due to long-standing bronchitis or emphysema. This chest is really larger than the natural chest during the most forced inspiration; it is also altered in shape, being rounded or barrel-shaped, the diameter from before to behind being sometimes as long as that from side to side; the back is convex, and the sternum is curved, so that the patient looks as if he were hump-backed; the upper part is rounded and large, whilst the lower is more contracted. If you watch the breathing, you will see how it has come about; owing to the bronchitis and emphysema, and consequent difficulty in expelling the air, the diaphragm has pushed up the lungs, and the chest, continually heaving its upper part, has become permanently expanded. It is a form of chest worthy of your notice and not to be overlooked, for it contains in its appearance the history of the patient.

Inequality of the two sides.—Now, having examined the chest as a whole, and observed whether it be malformed, look and see whether the two sides are symmetrical. One side may be larger than the other, which may indicate a pleuritic effusion, or a growth, or hydatid in the liver, or one side may be contracted or smaller, which is generally an old pleurisy, either occupying the whole side or a part. If the upper part be contracted it is very often associated with disease of the lungs, and indicates phthisis.

We next come to the mode of expansion of the chest, by observing whether the two sides dilate equally. This is very important to notice, since the impaired mobility of one side necessarily points to recent or old disease on that side; and it is also

important to take note of the unequal expansion of parts of the same side, as, for example, a deficient movement of the upper or lower part, and which generally implies the existence of a former pleurisy. You must also observe whether the ribs and diaphragm are doing their work in the right proportion, for there are causes, especially those existing in the nerve centres ruling over the respiratory process, which may either paralyse the movement of the chest or the diaphragm respectively, and thus we say the breathing is costal or diaphragmatic. Also in cases of emphysema and capillary bronchitis, where the lower lobes of the lungs tend to become airless; a want of due expansion of the chest is very noticeable at its lower part, while the upper part is heaving at every breath.

Mode of Breathing and Rhythm.—You will first observe if breathing be quickened. This may be simply nervous in persons who are well. If associated with acute illness, it should make you at once suspect some inflammation in the chest. If the increased rapidity have been constant for some time, you may suspect a chronic disease, as phthisis. Dyspnoea is difficulty of breathing, and the term should be used in no other sense. It means the cases where the air enters the lungs with difficulty, owing to impediment in the air-passages, and is therefore applicable to cases of laryngitis and bronchitis. A third form of altered breathing is seen in the case of breathlessness, shortness of breath, or cardiac apnoea. This is not dyspnoea; there is no difficulty in getting the air into the chest, but the breathless condition is due to the irregular manner in which the blood reaches and passes through the lungs. You must remember that there is an intimate relation between the action of the heart and the respiratory process. The heart beats four or five times to every respiration, and as much blood as is sent in on one side is received on the other. It is very evident, therefore, that to preserve the equilibrium any increased activity of one organ should be reciprocated by the other, and this occurs in active exercise, or in febrile conditions; but in any disease of the lungs inducing impediment to the flow of blood the heart suffers; it becomes overloaded, the venous system gorged, and serum at last exudes in the form of dropsy. In like manner, if the heart be acting irregularly, or be weak, and therefore cannot propel the normal amount of blood into the lungs in a regular manner, or cannot receive it in due quantity on the other side to propel it onwards, the respiratory process is interfered with, the due relation between the circulating blood and air is deranged, and the patient feels distressed or breathless. Of course the lung may be gorged at the later periods of heart-disease, and a real difficulty of breathing may ensue, but at earlier periods the condition is one of breathlessness or apnoea. The proportion between the respiratory act and the beat of the heart is as 1 to $4\frac{1}{2}$, since the number of expirations in a minute is 16, and beats of the heart 72.

The rhythm also may be altered. It may surprise you, when I say that very different opinions have been held as to the exact mode and time in which expansion of the chest takes place during breathing; but it is so, and the fact is owing to the difficulty we experience in attempting to measure accurately the movements of the chest, since, directly an attempt is made to do so, the subject of the experiment having his attention fixed on himself, the natural process is thrown out of gear. The graphic method has lately

been used, but this is also open to the objection named. You may remember this fact as near the truth—that, if the time of one respiratory act be divided into ten parts, five would be consumed in inspiration, four in expiration, and one in rest. I am speaking of the movements only; if you regard the breath-sounds heard by the ear, you will find that there is but one continuous or single respiratory murmur. In ordinary quiet breathing this is heard only during inspiration, no sound whatever being heard during expiration. In forced breathing, some amount of murmur may be noticed at the commencement of expiration, but if so, it is quite continuous and not to be dis severed from the sound heard during inspiration. If, then, sounds be heard during expiration, they are abnormal and denote disease. They are usually produced in the bronchial tubes, and therefore are not normal sounds occurring at an unusual period, but they are really new and morbid sounds. Expiratory sounds are always abnormal, and therefore especially to be noticed.

Palpation.—We now come to the next mode of examining the chest, and that is, by laying the hand upon it, or by palpation. We have two objects in view by this procedure; first, to ascertain the amount of movement in the chest, and, second, the absence or presence of fremitus. As regards the first, the hand will often distinguish what the eye cannot; of course, in well marked cases of disease, such as pleurisy, and especially with effusion, the non-expansile power of the chest is readily discernible, but occasionally there are mild cases of pneumonia or bronchopneumonia, especially in old people, where the ear can detect nothing, but the hand can readily appreciate the difference of expansion on the two sides. I have ascertained the existence of pleurisy in a patient lying insensible by this means.

Then, again, we lay the hand on the chest for another important reason, and this is, to ascertain the modification of the vocal fremitus. This is a most important physical sign, but constantly overlooked by students. In health, when we speak, the voice vibrates through the chest, and this thrill is felt when the hand is placed upon it. Now, in some cases, as in hepatisation of the lungs, this vocal thrill or fremitus is very commonly intensified, whilst in effusion of fluid it is altogether absent. The hand will not only appreciate the difference in vocal thrill, but it will often detect a pleuritic fremitus in acute pleurisy, or a bronchial fremitus in bronchitis, or a thrill in cardiac disease, more especially of the mitral valve.

Mensuration.—Under this head we include the actual measurement of the size of the chest by means of tapes and the measurement of its movements. We include, thirdly, a measurement of the air which can be breathed into the lungs, and which is also called the vital capacity. As regards the first, I will refer you to your books, where you will see various kinds of apparatus used for the purposes of measurement; some of these taking the form of the chest, and others, which are graduated, enabling you to compare the size of the two sides. There are also instruments which, by being placed on the chest, move the hand of a dial, and thus enable you to measure the amount of movement.

The vital capacity, or amount of air breathed, is taken by means of a spirometer; and I will here remind you of what you have already learned on this subject, because the facts are applicable to cases of

disease. You know that, when you breathe, the lung undergoes only a moderate amount of expansion and contraction; when you have expired to the utmost, the chest is still full of air-containing lung; just as a river still contains water when the tide has ebbed. This air, which corresponds to the difference in amount between that in the inspiratory lung and that in the expiratory lung, is called the tidal air. The air which remains in the lung after the most forced expiration, is styled the residual air. Now, in ordinary inspiration we do not inflate the chest to the very utmost, but if we do, we breathe in an additional, amount of air, and this in forced inspiration is called supplementary. Such a condition occurs when one lung is diseased or compressed, and additional work is thrown upon the other; and it is for this reason, therefore, very important to notice. You may also remember that when in the dead body you open the chest the lung collapses, but if it be taken out and examined, it will be found still to contain air, and it floats in water; this air is called the persistent air. In some cases, however, as in pleuritic effusion, every particle of air may be squeezed out of the lung: it is then a fleshy mass, and is said to be carnified. The amount of respirable air is the difference between that in the fully expanded lung and that in the most forced expiration—or the tidal and supplementary air together. The spirometer has been found of little use in practice, owing to the difficulty there is in making persons understand how to use it, and then again because the amount of expansion depends upon other circumstances besides the size of the chest; as, for instance, the muscular strength of the patient; thus, a person used to athletic exercises would show a higher range on the instrument than one whose chest was of equal dimension, but who was fat and had led a sedentary life.

(To be continued.)

JAGIELSKI ON THE VARIOUS PREPARATIONS OF KOUMISS AND THEIR USE IN MEDICINE.

Dr. V. A. Jagielski contributes two articles on koumiss to the *British Medical Journal* of February 4 and March 7. The following is an abstract.

Every educated person has heard that the Tartars drink 'koumiss,' the milk of their mares, in a state of fermentation, and that the Russian Government has established koumiss institutions in Samara, Orenburg, Moscow, Petersburg, &c., for a resort of treatment in chronic chest-diseases. We also know that in all those places mares from the Tartar steppes have been expressly imported. The original koumiss, therefore, is made from mare's milk; but the milk of all animals is convertible into koumiss; and in Dr. Jagielski's opinion, cow's milk, which comprises all the nutritive requirements of the human body, is an equally good raw material, if not better than mare's milk, because it affords facility for varying the composition and consistence of the koumiss produced, according to the indications of particular cases; besides, it offers the great advantage of being free from any disagreeable odour and taste, unlike mare's or goat's milk. The various sorts of koumiss used in Great Britain are: full, medium, whey, and diabetic koumiss, and 'Bland,' showing a series of consistencies from the thickest to the thinnest fluid. Qualitatively, however, the koumiss from different kinds of milk may be considered uniform.

The changes which koumiss undergoes while fermentation goes on in the bottles are represented in

three gradations, designated as nos. 1, 2, and 3. The fermentation, once started, will continue, no matter how cold the temperature, or how closely the koumiss may be corked in bottles. In all cases koumiss is a milk-like fluid; in its fresh (no. 1) state it is a still liquor, and has an agreeable sweetly acidulous taste; as it approaches the no. 2 gradation, it becomes more acidulous, assumes a sparkling character, and requires to be drawn from the bottle through a special tap. In no. 3, the sweet taste is entirely replaced by the acidulous, and the koumiss rushes through the tap in a rich creamy foam. These changes progress so rapidly in warm weather that the bottles should be kept in a cold cellar, and treated with the same care as Champagne wine.

A. or Full Koumiss is made from cow's milk, preserving the whole of the cheesy matter and as much of the butter or cream as is compatible with digestion and manufacture. It is adapted for cases of great emaciation and weakness of the digestive organs; when little liquid and no solid food can be taken; also for all complaints which are not of a febrile character, the bodily temperature especially not exceeding 100° Fahr., and for patients who have previously improved under the medium koumiss.

B. or Medium Koumiss is the artificial representant, as nearly as possible, of the mare's milk koumiss, and can be made by mixing ass's milk with cow's milk in the proper proportions, or by adjusting the natural components of cow's milk alone, so as to diminish the cream and butter and augment the lactose and salts, thus making the koumiss more easy of digestion. It is suited to delicate or sensitive stomachs, which revolt against the buttermilk taste of the full or A. koumiss, in which the cheesy matter proves too rich; and it is also a more sensitive koumiss, of more agreeable taste, so as even to satisfy a very capricious palate. The specific gravity of B. koumiss varies between 1.035 and 1.070 in its fresh state, though by the process of fermentation it may sink below 1.028, in consequence of the lactose breaking up into lactic and carbonic acids and alcohol. The molecular condition of this koumiss is so uniform, that the cheesy matter when separated in layers can easily be reduced, by shaking, to a homogeneous state, and no flakes are then noticeable, as in the mare's milk koumiss. In a well fermenting koumiss, the precipitated cheesy matter dissolves on the tongue like snow-flakes, with an acidulous and pleasant sensation. No wonder then that it does not give the stomach the slightest trouble in digestion or absorption, and is easily borne in larger quantities, so as to replace readily loss of flesh in wasting diseases.

Of this B. koumiss Dr. Jagielski presents the analytical results obtained by Wanklyn. A quart bottle of this (obtained from Messrs. E. Chapman and Co., the manufacturers in London) holds about 12,000 grains of koumiss. It was examined when twelve days old; spec. gr. at 62° Fahr., 1028.

| | |
|----------------------------|----------------|
| Water | 10,662 grains. |
| Alcohol | 192 " |
| Caseine, albumen | 128 " |
| Lactose | 582 " |
| Lactic acid | 130 " |
| Fat | 36 " |
| Ash | 90 " |
| Carbonic acid | 180 " |
| <hr/> | |
| 12,000 | |

The 90 grains of ash contain, approximately, 60 grains of phosphate of lime, and 30 grains of mixed

chlorides of sodium and potassium. 970 grains of solid respiratory and plastic food are, approximately, contained in every quart bottle, according to Wanklyn, and each of its elements is in a state to promote digestion of the others by the feeblest stomach. The following analysis of mare's milk koumiss, made by Hastier, a chemist of Moscow, may be compared with one of E. Chapman's medium cow's koumiss, in London, made by Wanklyn.

Mare's Koumiss. Medium Cow's Koumiss.

| | | |
|--------------------|----------------|----------------|
| Alcohol . . . | 1'65 per cent. | 1'60 per cent. |
| Fat . . . | 2'05 " | 0'30 " |
| Milk-sugar . . | 2'20 " | 4'85 " |
| Lactic acid . . | 1'15 " | 1'08 " |
| Caseine, albumen . | 1'12 " | 1'07 " |
| Ashes or salts . | 0'28 " | 0'75 " |
| Carbonic acid . | 0'785 " | 1'50 " |

Thus the caseine in both kinds of koumiss is the same to a fraction; the butter or fat in the medium koumiss is much less, for the simple reason that it is not advisable to send out the koumiss *à longue course* with all the fat contained in the milk, as it decomposes too quickly into butyric acid, which is deleterious to the digestive organs. Further, the lactic acid and alcohol show no difference worth considering; but the lactose in the medium koumiss is twice as much as in mare's koumiss, if Hastier's analysis deserve as full credit for correctness as Wanklyn's does, whose reputation as an analytical chemist is undeniable.

C. or Whey Koumiss, contains neither butter nor caseine, but some albumen, lactose, lactic acid, alcohol, the salts, and carbonic acid. It may prove useful as a beverage in diseases with even strong febrile reaction, with copious or excessive expectoration, perspiration, or diarrhoea, either in plethoric or in strong constitutions, which do not require an increase of weight, or in patients with inflammation or fever. Whey supplies the body with but little nourishment, and therefore it can never be applied to the purpose of a proper plastic treatment; but it decidedly promotes the appetite and digestion, and, as a cooling and refreshing drink, it calms irritation.

The 'Sparkling Bland,' a diluted and still more pleasant form of whey koumiss, may, in febrile disease, be used as a refreshing acidulous drink; and it will prove more convenient, as bland will keep for a long time, and may be agreeably flavoured with ginger, lemon, orange, &c.

D. or Diabetic Koumiss, contains, according to Wanklyn's analysis, 1'6 per cent. of alcohol, 1'1 per cent. of lactic acid, and not more than 1'1 per cent. of lactose. It is particularly suitable for the treatment of diabetes, to increase weight, to allay thirst, to excite the action of the skin, &c.; and it appears less important how much urine and sugar are excreted, as long as the patient's weight and strength are increasing; besides, we need not restrict the diet in the usual severe way. If the skimmed milk treatment, the butter-milk cure, or Professor Cantani's lactic acid treatment, have given such good results, koumiss is still of more value, as it acts as a ferment in decomposing within the body all saccharine matter, and is an easily absorbable and strengthening plastic nourishment; otherwise Dr. Jagielski cannot explain its beneficial effects on this disease, even as *ultima ratio*, when the tongue appears parched, and the patient seems skin and bone and thoroughly exhausted. The complication with lung-disease appears a forcible indication for its imme-

diate use, as life will be prolonged under this treatment. The koumiss ought to be about a week old, sour and well sparkling, and the patient ought to take daily muscular exercise in open air, making the koumiss his principal or exclusive beverage as soon as a taste for it has been acquired; the diet ought to consist chiefly in meat. Glycerine, if ordered together with the koumiss, may be advantageously mixed with it in the proportion of two ounces per quart bottle of the koumiss, with which it becomes intimately united; in this way nausea and diarrhoea from the glycerine, when given alone or in water, are prevented.

Dr. Jagielski finds that koumiss exerts a striking remedial power in chronic gastro-catarrh arising from any causes, even from the abuse of alcoholic drinks, the use of tonics, astringents, styptics and sialagogues, or the habitual taking of opium. It stimulates digestion without affecting the head; it leaves the head clear for brain-work, and generally strengthening memory and intellectual power. In pulmonary consumption (chronic form) the first stages are most benefited by koumiss, but in the febrile phases of phthisis it is contraindicated like other nourishing diet, and should be replaced by whey koumiss, bland, salines, quinine, etc.; especially as long as the bodily temperature is much above normal, and does not show any marked differences between morning and evening. The greater these differences the better the effects from koumiss. If in eight or ten days the body do not begin to gain weight, the temperature do not show a declining tendency, the tongue do not clear, the appetite do not improve, then the koumiss will be of as much or as little use as any other treatment or medicine. In many of the secondary symptoms, such as dyspnoea, cough, weakness, emaciation, night-sweats, diarrhoea, etc., even where they are so strong as not to correspond with the topical process of the malady, koumiss is a prompt and powerful check to development of the morbid process; and many other cases of debility, in consequence of excessive or protracted copious secretion of mucopurulent matter or severe hæmorrhages from lungs, stomach, bowels, or after operations, childbed, lactation, find a comforting restorative. It is a physiological property of koumiss to lessen all discharges, but to stimulate diuresis and a healthy action of the skin. On the fifth or sixth day, the change in the quantities of the various salts excreted begins, and the amount of chlorides and of urea in the urine diminishes—these being probably again used to build up the new tissues; the exhausting night-sweats cease, and the quantity of urine secreted is increased in the most striking manner, when, also, all cloudy, turbid, and thick appearances of the urine change into a limpid state; in warm weather, diaphoresis takes the place of diuresis. Koumiss is therefore useful in catarrh of the urinary system with copious deposits of any kind, and in hæmaturia, but principally in catarrh of the bladder with copious mucous or mucopurulent sediment; on vaginal and urethral discharges it appears to have the same checking effect. In albuminuria it is mostly of benefit, especially against the accompanying dropsy; at all events, it improves the general nutrition and strength. In chronic pharyngitis, laryngitis, and more especially in bronchitis, even when relaxation and general weakness are very great, koumiss appears to be more beneficial than even Ems water, the properties of which it exhibits *plus* a great nutritive power. In copious expectoration, particularly from large vomicae, koumiss

will surprise anyone who will measure the expectoration in a graduated spittoon glass partly filled with water. The cavities dry out or contract, the mucous expectoration gradually falls to a minimum, and the strength and flesh increase in consequence of a more facile digestion and nutrition. The regular use of koumiss in chronic complaints should extend from six to eight weeks, at the average taking two quart bottles per day, more or less; and should there be a recurrence of any of the symptoms, they may be checked at once by a repetition of a short course, or even a few bottles only. Should the koumiss prove too acidulous, a little sugar or syrup with some fresh milk will correct its taste; a small quantity of Champagne wine with it will augment the alcohol in a very pleasant way, if necessary. The weaker the patient is, the more frequently he ought to take small quantities of the koumiss, every 15 or 20 minutes an ounce; with his meals a wineglass full, and as much for tea and breakfast, increasing the doses gradually and in proportion to its good effects. All other fluids, oily, pickled, salted, smoked food, and all strong condiments, should be avoided during its use. When the secretions are impaired, as in constipation, biliousness, catarrh of duodenum and bile-ducts, &c., no. 1, or fresh full koumiss, must be employed, because of its mild aperient effect; or no. 2 and 3 koumiss must be mixed with half of fresh sweetened milk at the moment of drinking, to produce the same aperient effect. No. 3 is astringent. In conclusion, koumiss, although not a specific against consumption, is an easily digestible excellent nourishment, a pleasant dietetic remedy, which rapidly improves digestion and nutrition, and is particularly suited to heal the relaxed condition of the mucous membranes, and coincidentally to increase strength, weight and good spirits. To mention all diseases for which the koumiss treatment is applicable would be irrational, as every disease may reduce nutrition and strength, even the fracture of a bone or a simple cold, and in such conditions koumiss is indicated. It is now settled beyond question that it is wonderfully suited as a form of nourishment for badly nourished, wasted, rachitic or scrofulous children, or for convalescents; and also that it can often cure cases of obstinate chronic diarrhoea, or old catarrh, provided the patient like the remedy. For purely drug substances, and especially for cod-liver oil, it is an admirable succedaneum.

KROENLEIN ON THE TREATMENT OF WOUNDS.*

The treatment of wounds is one of the great questions of surgery of the present time, and Dr. Kroenlein's book is a valuable contribution to the efforts made by modern surgeons to answer this question in a satisfactory manner.

The method of open treatment of wounds was first recommended in Germany by Bartscher and Vezin, and has afterwards been advocated by Professor Burow of Königsberg.

Dr. Kroenlein compares two well-marked periods, where different treatment has been adopted in the surgical wards of the hospital of Zürich: 1. the period of 1860-1867, under the direction of Professor Billroth,

where the wounds were covered in an ordinary way; and 2. the period of 1867-1871, under the direction of Professor Rose, where the open treatment was executed in a thorough methodical manner.

In order to have some categories for comparison, he has selected out of the whole number of surgical patients the following classes of cases: 1. amputations: 2. extirpations of the mamma: 3. compound fractures: 4. accidental surgical diseases.

The results of the two series were, as regards mortality per cent., as follows:

| | First Period. | Second Period. |
|---------------------|---------------|----------------|
| Thigh | 86.1 | 35.7 |
| Leg | 58.3 | 18.1 |
| Foot | 35.2 | 20.0 |
| Upper-arm | 55.5 | 14.0 |
| Fore-arm | 16.6 | 0.0 |
| Hand | 0.0 | 0.0 |

Critical researches by the author show, that this remarkable result was due neither to the age and sex of the patients, nor to the method of amputation, but entirely to the after-treatment.

The bleeding vessels were carefully tied. Secondary hæmorrhage occurred less in the second period than in the first; but, corresponding to the greater number of ligatures, healing by first intention was more rare in the second. Necrosis of the stump occurred in the first period only in 21.3 per cent. of the cases; in the second in 32.7 per cent. Retention of pus was observed in the first period, in 11.4 per cent. of the cases; in the second only in 3.4 per cent. The time of healing was in general longer during the second period; amputations of the leg and the upper extremity required three weeks more for healing under the open treatment, while amputations of the thigh required nineteen days less during the second period.

The cases of extirpation of the breast had a mortality of 32.3 per cent. in the first period, and 13.6 per cent. in the second. The time of healing for this operation was 43 days, if treated in the ordinary way; 67 days under the open treatment.

Of the cases of compound fractures which were treated in the conservative way, 25.5 per cent. died in the first period; 21.5 per cent. in the second.

Of accidental diseases, there occurred pyæmia and septicæmia during the first period in 146 cases amongst the total number of 4,000 patients; during the second period in 19 cases out of 2,300; thus giving 3.65 per cent. for the first, and 0.8 per cent. for the second period. Respecting only those cases referred to in the above classes, viz., the amputations, the extirpations, and compound fractures, pyæmia occurred amongst the 260 cases of the first period in 22.6 per cent., amongst the 172 cases of the second only in 6.9 per cent.

Erysipelas more frequently occurred in general under the open treatment; namely, in 148 cases out of the 7,000 patients of the first period, or 3.7 per cent., and in 127 cases out of the 2,300 patients of the second period, or 5.5 per cent. Notwithstanding, this disease was less often observed in the amputated of the second period (7.0 per cent.) than in those of the first (9.2 per cent.). Respecting the other categories, the first period showed an advantage over the second. Dr. Kroenlein thinks that ventilation, which was more energetically executed in the second period by opening the doors and windows of the wards, may have had an influence on the originating of this disease. The table of temperatures of the wards sometimes shows a temperature of 40° to

* Die offene Wundbehandlung, nach Erfahrungen aus der chirurgischen Klinik zu Zürich. By Dr. R. U. KROENLEIN, Zürich: 1872.

50° Fahr. which, we must agree, may not only be disagreeable but also noxious to open wounds. However, the imperfect state of ventilating and warming institutions of the infirmary did not admit a higher temperature without corrupting the air.

There can rarely be a better opportunity of comparing two different methods and of proving what the effect has been than this; because, except the treatment, there was no change in the hospital as regarded the wards, beds, nourishments, ventilation, water-supply and other arrangements.

The numbers referred to are large enough to refute the objection, that a greater number would perhaps have shown a different result; and notwithstanding in the first period there were 140 amputations and only 85 in the second, and we may suppose that all the wanting 55 cases would have died, even then the result of the second period would not have been worse than in the first.

The advantages of the open treatment seems to be the following.

1. There is no pressure or constriction by dressings.
2. An irritation of the wounds by changing the position and external applications is avoided.
3. There is no danger of infecting the wounds by impure articles.
4. The danger of retention of matter is small.
5. The state of the wounds may be controlled at any time by simply lifting the coverlets.
6. As healing by the first intention is given up, as many ligatures may be applied as are desirable, and thus secondary hemorrhage may be better avoided.
7. The air of the wards is not infected by emanations from the dressings, as is the case in other methods, except Lister's.
8. There is less need of material for dressings, therefore less expense.

It seems that these advantages will recommend the open treatment not only to large hospitals, where constant inspection by medical men is possible, and to medical schools, where regular observation of the wounds by the students is very desirable for instruction, but also for the practice of war, where the material for dressings is often bad and infected, or not to be got in a sufficient quantity.

There are two points in which the open treatment is certainly inferior to other methods, specially to Lister's antiseptic method; viz., the renunciation of healing by first intention, and the rather frequent occurrence of erysipelas. This latter, however, may be avoided by sanitary means. And if a surgeon think that healing by first intention is possible in a special case, he may adopt for this case any other method which he may think best.

Dr. Kroenlein, indeed, has done well to carry out the open treatment methodically and rigorously in all cases, because without this we should not have such an evident result from a statistical as well as a critical point of view.

We would warmly recommend any one who is not satisfied with this short extract to read the monograph of Dr. Kroenlein himself, because every result is drawn up with great accuracy and circumspection, and the whole gives the impression of perfect credibility. P. SCHLIEF, M.D., Berlin.

CLINICAL MIDWIFERY.

ABSTRACT OF A LECTURE ON PUERPERAL ECLAMPSIA, DELIVERED AT THE HÔPITAL SAINT-ANTOINE, PARIS. BY M. PÉTER.

Puerperal eclampsia is one of the most important affections in obstetric pathology, and has always been a subject giving rise to endless controversies and experiments, mostly from the etiological, pathogenetic, and natural points of view. M. Péter, whose post at the St. Antoine Hospital allows him exceptional opportunities for studying this disease, has given two most interesting lectures on it, of which we present the following summary. In the course of his lectures M. Péter strongly recommends the perusal of the excellent article, by M. Bailly, in the lately published *Dictionnaire de Médecine et de Chirurgie Pratiques*, to which he renders a just meed of praise. It is constantly advanced as a fact that all pregnant and eclamptic women are albuminuric; that the albumen may disappear for some hours, and that eclampsia in pregnant women without the presence of albumen forms a very rare exception. Thus there may have been recorded six or seven cases of eclampsia without albuminuria.

Two questions immediately arise. The first is what is the reason of this frequency? To this the reply is, that there is a larger mass of blood in circulation. The second is, as to whether cases of eclampsia have become more common during the last thirty years. To this the evidence of statistics gives an affirmative reply. The hypertrophy of the heart during pregnancy shows the increased amount of blood in circulation. The demands of the uterus are augmented, and the blood of the mother has to supply the nutrition of the fœtus. Therefore the maternal organism ought to benefit by this larger volume of blood; and, as a matter of fact, the woman does present both the appearance and the reality of plumpness. This fact being established, what then are the accidents which are likely to occur in such a contingency, the organs liable to be affected being the lungs, liver, and kidneys?

With regard to the lungs; as the mother is obliged to make blood for two, we find pulmonary oppression, and when this symptom is increased, hæmoptysis. If the heart be diseased, with presumable mitral insufficiency, we meet with double pulmonary congestion. These facts declare themselves and these accidents appear towards the fifth month of pregnancy. With regard to the liver, we generally find simple icterus; acute icterus is uncommon.

We now proceed to consider the accidents to which the kidneys are liable during the pregnant state. In the same way as the mother makes blood for two, so she makes urine for two. The analyses of the urine and its elements demonstrate that there is a larger quantity of urea in the pregnant woman; and M. Quinquaud has found that, instead of 22 to 24 grammes in the twenty-four hours, she eliminates 30 to 38 grammes of this substance. A larger quantity of blood implies greater pressure and consequently more filtration, when not only albuminuria, but discharge of serum with the urine occurs.

According to the writings of Charles Bernard and the negative deductions he has drawn from his experiments, urea is not the cause of eclampsia, any more than is carbonate of ammonia. Neither is it uræmia,

THE *Chicago Post and Mail* gives the following as the immediate cost of a first-class baby:—Physician, \$50; midwife, \$25; wet nurse, \$50; dry nurse (one year), \$150; clothing, \$200; baby carriage, \$25; total, \$500.

nor ammoniæmia nor creatinæmia; but, according to M. Péter, creatinæmia. M. Quinquaud, who has made three analyses, found, instead of 6 parts of extractive matters, 21 per cent. in the first, 19·2 per cent. in the second, and 18·3 per cent. in the third.

The frequency of puerperal urinæmia has been increasing, a fact proved by M. Charpentier's inaugural thesis, in which he gives the following statements compiled from the records of the Hôpital des Cliniques during thirty-eight years: From 1834 to 1843, seventeen cases; for 1844 to 1853, twenty-seven cases; from 1854 to 1863, thirty-five cases; from 1864 to 1871, fifty-four cases.

MM. Andral, Gavarret, Becquerel, Rodier, and Reynauld have demonstrated that pregnant women have fewer red corpuscles, whence it has been concluded that all pregnant women are anæmic. M. Reynauld has analysed the blood of thirty-four pregnant women; the normal state of the blood-corpuscles is 127 per 1,000, but this observer counted 145 in one instance, 127 in another, from 125 to 120 in six cases, and from 120 to 195 in twenty-six. Thus it is evident that one-fourth escaped anæmia; besides which, before having arrived at that conclusion, it would have been necessary to analyse the blood of those women before they had reached their physiological state for the time being, in view of the anæmia possible before, during, and after pregnancy. The anæmia of pregnant women does not rest on any logical interpretation, and tocologists commit a *petitio principii* when they refer pulmonary oppression, spitting of blood and albuminuria to anæmia, by referring the eclampsia of pregnant women to anæmia of the bulb. This affection has also been termed serous plethora, a term to which we give our adhesion; but then the patient has serous blood: that is to say, blood less rich in corpuscles, giving rise to congestions of the liver and kidneys, which leads to icterus, voiding of serum, &c. If the bile were secreted by a gravidly congested liver, M. Péter believes that we should find in it serum, leucocytes, and blood-corpuscles.

The question is briefly as follows. Must we prevent congestion in the region of the kidneys? To answer this question, we must divide it into two branches: 1. How to foresee the accidents; 2. How to prevent them. For the first object, M. Péter recommends that the urine of all pregnant women should be examined. If, on the one hand, he note the presence of serum towards the fifth month, and, on the other, symptoms of cephalalgia, he is on his guard. The headache is very painful; it is seated in the anterior portion of the cranium, rarely in the occiput; at first it is fugitive, only appearing at certain times, and subsequently becomes persistent. 'Unhappy is the patient,' says M. Péter, 'in whom this symptom becomes persistent.'

After headache, visual troubles come on, troubles which consist in a difficulty of grasping the outlines of objects. The patient is unable to read for many minutes at a time, and she vomits if she wish to continue reading. She sees coloured spots (irisation) in consequence of want of accommodation, and may subsequently be affected by amblyopia, hemiopia, or amaurosis, going on to total blindness—a stage when the attack of eclampsia is not far off. The ophthalmoscope gives no indication; the transparent media are intact, and there is nothing in the retina. The hyperæmiæ, which cause these functional troubles, occur in the cerebral centres. M. Bailly has observed

a little suffusion in the conjunctiva, especially at the level of the oculo-palpebral folds, a kind of serous chemosis.

There are other prodromata equally conclusive with those already enumerated, one of them being a feeling of oppression at the epigastrium, as if there were continuous pressure on the epigastric cavity. This may probably be a species of aura seated in the pneumogastric nerve, a view of the case warranted, in M. Péter's opinion, by that other important and significant phenomena, dyspnœa. Vomiting forms another highly important symptom. The attacks are frequent, and the matter ejected consists of stomachic mucosities, bile, and food, when the sickness comes on after a meal. Finally, vertigo, dulness of the intellect, insomnia, or comatose sleep and restlessness, are observed.

Having thus enumerated the prodromata of the eclamptic attacks, M. Péter proceeds to consider the causes of urinæmia, which have been classified as:—1. The compression of the inferior vena cava and the renal vena by the gravid uterus; 2. Double pregnancy; 3. Triple pregnancy; 4. Rickets. These eclamptic attacks mostly come on from the fifth to the ninth month, and especially in the ninth month.

On this point M. Péter's conclusion is, that the congestion is in direct relation to the quantity of blood in circulation, and the quantity of blood is in direct relation to the double or triple alimentation which the maternal organism is obliged to bear, and which it must supply. The greater the functional need the greater the purificative need; whence arises a functional hyperæmia in proportional relation to the needs of two or three organisms. M. Péter, taking heed of the most salient facts, recommends blood-letting as a preventive measure, which is also advised by Cazeaux and Beau. The latter only takes away 60, 90, or at the most 120 grammes; M. Péter makes his minimum quantity 150 grammes, with the addition of the removal of blood by cupping in the region of the kidneys.

Bloodletting is also extolled as a curative measure by M. Péter, MM. Depaul, Dubois, and Cazeaux; it does not always cure, but it is sure to give immediate relief. In reference to this practice, Holz wrote to M. Charpentier that 'of all the means employed, bleeding has proved the least unreliable.'

A second method is to give emetics in contra-stimulating doses (*doses räsoriennes*). The third plan is the use of anæsthetics, particularly chloroform, a plan which has its partisans, its neutrals, and its enemies; that is to say, it has been powerful in the hands of the first-mentioned, useless with the second, and mortal when employed by the last. As surgical treatment, M. Péter recommends artificially induced accouchement, especially where the medical treatment has failed.

Eclampsia is a most serious affection. A great proportion of the sufferers from it die, and if they recover the cure is not complete, and Bright's disease is a certain result. Amongst all the accidents to be dreaded as likely to carry off the patients, one of the most serious is uterine hæmorrhage, a result of the typhisation of the blood, an accident first observed by Blot, and which cannot be arrested by any expedient whatsoever.

Retroflexion of the Uterus, and its Relation to Conception and Pregnancy. By Dr. Stadfeldt. (*Ugeskrift for Læger*, Nov. 8.)

PSYCHOLOGY.

THOMPSON DICKSON ON THE FUNCTIONS OF BRAIN AND MUSCLE CONSIDERED IN RELATION TO EPILEPSY.—The object of the writer, Dr. J. Thompson Dickson (*Journal of Mental Science*, October, 1873), is to discuss some of the recent opinions as to the nature of epilepsy, and in particular those of Dr. Hughlings Jackson, who regards the epileptic phenomenon as the result of a 'discharge' from a damaged portion of the brain, which he speaks of as a 'discharging lesion.'

Dr. Dickson's own views have been already stated in the *British Medical Journal*, November, 1867, in the *Journal of Mental Science*, July, 1869, and in the *British Medical Journal*, June, 1870, and he is of opinion that: 1. Epilepsy is a contraction of the cerebral capillaries and small arteries, the order of its stages in epileptic attacks being, first, irritation of the brain, either direct or secondary to exhaustion; secondly, contraction of cerebral capillaries and small arteries; thirdly, cerebral anæmia, and consequent loss of consciousness; 2. The muscular contraction and spasm, with all the phenomena of epilepsy, are secondary, and not essential or constant, but are all manifestations of imperfect nervous control, or a loss of balance between the nervous and other systems.

On certain points pathologists are agreed. We know with certainty that the seat of the lesion or lesions is the surface of the brain. The views of Drs. Bright, Wilks, and H. Jackson on this point are confirmed by Dr. Ferrier's well-known experiments by faradisation applied to the cerebral surface. And that there is a condition of anæmia and contraction of the vessels at the time of the seizure, is proved by the experiments of Kussmaul and Tenner, by Dr. Dickson's own, and by observation of the pallor associated with the invasion of epilepsy.

Dr. Dickson disputes Dr. Jackson's theory that the normal function of nerve-tissue is to store up and expend force, which theory, he says, involves the notion that the nerve-force behaves as static electricity, and is capable of being accumulated in the cells of the grey matter, as the electricity is accumulated and discharged from a plate or jar, which he thinks not only improbable, but impossible. 'That the nerve-cells are capable of storing up motion in some mode or modes, is only in a very limited sense true; the principal modal changes which go on in the brain are chemical.' The function of muscle is contraction and movement, and, when muscles are perfectly normal, they will, if liberated from control, perform their function spontaneously, and will continue to perform it until their potential energy is exhausted. The new-born infant, and the new-born cow or horse, move, not from mandates sent to their muscles from their untutored brains, but from spontaneity, from the tendency of the healthy muscles to perform their function. The seat of control over each muscle is the region or spot in the grey matter of the brain wherein its first motions were recorded, and which thenceforth was destined to become the controlling centre of its motion. That we may have loss of function of any organic tissue is perfectly true, but that we ever have over-function does not seem to be strictly physiological, or possible; that a tissue like the brain should 'store up more force than in health,' seems also impossible. The function

of the brain may be interfered with, and become irregular or cease; and as the healthy brain's function is not to give out discharges, but to maintain control, so the badly nourished brain, or the atrophied brain, loses its power of maintaining control, and the function becomes imperfect or irregular, and under some circumstances, altogether ceases. A fact which is distinct and clear is, that the seat of the expenditure of force in any movement is in the muscles, and not in the brain. A fact recorded by Galvani, and verified by Niobi, is that the set of the current in the nerves during muscular contraction is not in a direction from the brain to the muscle, but from the muscle to the brain. It requires no direct nervous stimulus from the brain to cause muscles to contract. Healthy and well-nourished muscles will contract, as is their wonted function when the brain is removed altogether, as in the decapitated. We may, therefore, from the evidence we have, conclude that the muscular contraction and spasm in epilepsy is the necessary consequence of a loss of cerebral control. If the damage be in one convulsion only, we may have a local muscular contraction; if the lesion be in more than one, we may have contractions in several regions, or the whole brain may become anæmic, and the convulsions general.

Epilepsy, then, is not a display of sudden and ruthless expenditure of stored-up force, but is the manifestation of a condition of weakness and exhaustion, the primary seat of which is the surface of the brain. The exhibition of strength, we further see is the loss of the potential energy of muscle, which it is the function of the nervous tissue to control and guard; and in the muscular exhaustion is to be sought the cause of the temporary paralysis which often succeeds epilepsy.

G. FIELDING BLANDFORD, M.D.

LUBIMOFF ON LESIONS OF THE BRAIN IN GENERAL PARALYSIS.—Lubimoff's paper, published in Virchow's *Archiv*, vol. lvii. 1873, is founded on fourteen carefully reported cases of general paralysis, which presented themselves in Meynert's Psychiatric Clinique. The full history of each case is given, along with the *post mortem* appearances, naked eye and microscopic. Thin sections were made from specimens hardened in a 2 per cent. solution of bichromate of potass; they were coloured with carmine, and set up in gum Damar. The cortical substance of the frontal lobes was usually examined, and in some cases that of the parietal, occipital, and insular lobes, the cornu Ammonis, and other portions of the encephalon. Lubimoff reports one case in which a sort of cicatrix or wedge-shaped induration was found on the right hemisphere of the cerebellum, implicating two lobules which were glued together by a substance which unmistakably consisted of connective tissue. The molecular and nucleated layers were thinned, and Purkinje's cells almost obliterated. For the normal structure, a dense 'felt-like' substance was substituted, in which nuclei were imbedded, and which was intimately connected with the walls of the blood-vessels. Around it, the undestroyed cells of Purkinje appeared plainly sclerosed. Lubimoff supports Meynert's observations as to the intimate relation of brain-lesions with hyperæmia; that they never occur apart from it, and may be regarded as a consequence. In some cases, the vessels showed indications of obstruction during life by means of thrombi, due to metamorphosis of blood-corpuscles

into molecular masses, with here and there distensions filled with corpuscles, and in extreme cases actual rupture of the vascular walls and diffusion of the periphery (*Zerstreuung im Umkreis*) in the parenchyma of the organ. There were also found in all the fourteen cases, on and around the vascular walls, pigment-deposits of various sizes and sometimes of very considerable extent, which are taken to be evidences of previously existing congestions. Apart from these consequences of hyperæmia, the walls of the vessels presented themselves altered and thickened; their normal coats and muscular striæ being destroyed, and the thickened walls appearing to consist of a homogeneous mass, waxy in appearance. On this Lubimoff bases his term of 'waxy degeneration' of the vascular walls. The nuclei, especially at the bifurcations, appeared proliferated. Lubimoff cannot determine whether in general paralysis the vessels thicken themselves by an absolutely new growth.

The special characteristic of paralytic dementia presents itself in the changes of the nuclei of the neuroglia, which show themselves in the brains of such subjects wonderfully increased in quantity, to a degree which, according to Lubimoff, must be accepted as a pathological product, as preparations of healthy brains and of those taken from the subjects of other neuroses (*e.g.* extreme melancholy and mania), show but a slight amount of neuroglia-corpuscles in the cortical substance. (In the opinion of Boll, who has inspected Lubimoff's preparations, this observation is of the highest pathological value.)

What Lubimoff describes as nuclei of neuroglia are very fine Deiters' cells, which are well known through the works of Golgi, Jastrowitz, and Boll; his description is entirely in consonance with that of these writers, and he arrives independently of them at the result, that a peculiar intimate connection exists between the vascular walls and the Deiters' cells, as in these cases their processes are peculiarly well pronounced.

Lubimoff found the Deiters' cells most abundant in the inner layers of the gray matter bordering on the medullary substance, and on the outer layer contiguous to the pia mater; in which positions they were so numerous, that the normal appearances of the structures were lost, and their place taken by the felt-like net-work, which, as in the case of the cerebellum previously described, can only be ascribed to the interlacement in various directions of the processes of the Deiters' cells.

The morbid changes of the nerve-cells are placed under two heads; they are liable either to a degree of swelling and subsequent collapse, or to a tendency to sclerosis. In the first case, the changes of the nuclei consist in dilatation of the nucleus and diminution of the quantity of the 'surrounding protoplasm;' occasionally the nucleus subdivides so that two are found in one cell, and are not readily amenable to carmine, which Hoffman already has shown to be characteristic of the morbid ganglion-cell. Meynert considers that the protoplasm of such cells shows different degrees of molecular degeneration. The sclerosis of the cells changes them into a homogeneous wax-like mass, in which the nucleus is no longer to be distinguished, but occasionally the nucleolus. The protoplasm of such cells loses its normally fine granular appearance, the cells appear strongly refracting, with sharply defined dark contour. The changes in the axis-cylinders found by Lubimoff consist in thickening and hypertrophy.

It is deduced from these anatomical facts that as regards the pathological processes in general paralysis, the origin of the psychical disturbances is to be sought for in the anomalies of blood-distribution and its consequences. With the incidence of hyperæmia begin the changes in the nutrition of the nuclei of neuroglia, which leads to an increased development of their elements which, in their turn, take on morbid action. This is proved by the modification of the morbid appearances, according to the length of time during which the case has lasted. The treatise concludes with deductions as to how the clinical symptoms of the individual cases are explicable by their special anatomical conditions. Lubimoff agrees with Westphal that disease of the cord is a constant accompaniment of general paralysis; but he differs from him and Simon in holding that the disease can exist without pathological changes in the brain. On the contrary, he endeavours to establish a chronic inflammatory condition of the connective tissue of the cortical substance as the anatomical lesion of general paralysis.*

[Are these observations quite novel, and are the appearances described peculiar to general paresis?]

J. BATTY TUKE, M.D., Edinburgh.

RABENAU ON THE RELATION OF GRANULAR MYELITIS TO PROGRESSIVE PARALYSIS OF THE INSANE.—Dr. Rabenau (*Archiv für Psychiatrie*, 1873) says that the picture of progressive general paralysis of the insane was originally drawn from clinical experience, and one understood by it a summary of symptoms in part psychic, such as more or less advanced dementia, large delusions, &c., in part corporeal, such as lesions of motility and sensation. The psychic symptoms were most striking and accordant with each other, whilst the bodily ones were, in some instances, very different. There would be the most severe paralytic appearances in one individual, whilst in another, characteristically affected in mind, the bodily symptoms might be quite absent. Hence in these cases the delirium was generally accounted the necessary symptom, the bodily symptoms as accidental; and thus great difficulties were placed in the way of pathological investigation, for, just as the almost constant appearance of paralysis and excitement, in the most various nerve-territories, showed that here, rather than in other psychoses, palpable changes in the central nerve-organs would be found, so did attention become directed chiefly to the brain-convolutions and their connections, the membranes, on the supposition that both sets of symptoms would thereby be explained. Westphal took another view, by taking symptoms which appear in only a few paralytics, and which are peculiar to one neurosis, viz. tabes. Since he found that in many paralytics precisely the same symptoms occurred as in tabes, the probability was that a similar pathological state existed. Anyhow, he was able to show that, in such paralytics as exhibited similar symptoms to those of tabes, a gray degeneration of the posterior columns of the cord would be found. Of course this gray degeneration accounted only for the symptoms during life of the tabes; for the rest it afforded no explanation. A further step was now made, as follows. The above-named paralytics present symptoms that are constantly found in chronic affections of the spinal cord, such as bilateral weakness of the extremities, lesions of sensibility of the spinal nerves,

* Boll in *Centralblatt für die Med. Wiss.*

paralysis of the sphincters, &c. Westphal then asserted, on the ground of his investigations, that where no gray degeneration could be found there was present another disease of the cord, characterised, in fresh preparations, by granule-cells, which, as a rule, selected the lateral columns. In preparations steeped in bichromate of potash, the diseased parts were more deeply coloured than the healthy, and this lesion was found in all paralytics where the gray degeneration was absent. The question of the connection with the cerebral symptoms of progressive paralysis he left open. Of course the spinal symptoms were only accounted for, and there must be other changes in the body to account for the brain-symptoms. It has been objected to Westphal's investigations that the disease of the cord existed in those who had never suffered from general paralysis, and also that it was not universal in all cases; but it only should be sought for in those where during life the symptoms are present which depend on such lesion. If we are to agree with Westphal in the general occurrence of spinal disease in progressive paralysis, we must either drop entirely, or greatly limit, the clinical idea of what this paralysis is. In the first place, in the cases where the diagnosis of progressive paralysis is made, or the psychical symptoms do not belong to the category, we must connect the myelitis with the symptoms of paralysis alone, and, where these are wanting, there is no myelitis. Again, we must not include chronic alcoholism, which resembles progressive paralysis somewhat in the bodily symptoms, for there are both difficulty of speech and muscular weakness. Those cases too must be excluded, where tumours exist and cause symptoms much resembling progressive paralysis, but which are quite explicable by the morbid growth and not by a primary myelitis. After thus weeding the many classes of paralytics, there still remains a large number in which disease of the cord is constant. Dr. Rabenau gives twenty-six cases, agreeing with Westphal and Sander (but he thinks that the coloration test by bichromate is not always to be depended on), and whilst allowing that the cord-disease can only account for the cord-symptoms, acknowledges that, if all the symptoms are to be explained pathologically, a lesion must be looked for in the brain, which is connected in some way with that of the cord; if this were found, the cord-disease might be deemed secondary, just as it comes on secondarily in tumours of the brain, &c. Dr. Rabenau's work has been done with reference, first to certain brain-diseases which stood in direct connection with the disease of the cord, and secondly to the disease of the connecting parts, the crura, pons, and pyramids. He found in two persons whose symptoms during life could not be distinguished from those of other paralytics, that in the radiating fibres between the corpus striatum and thalamus, and even extending over the valve of Vieussens, there were demonstrable granule-cells. If instead of these there had been a softening of the same extent, the myelitis would undoubtedly have been declared secondary, and all the symptoms during life ascribed to it. In his report of the twenty-six cases, he has only noticed the granule-cells which are found lying free in teased-out preparations, not regarding those adhering to the walls of the vessels; for it is agreed generally that the granule-cells in the vessels of the cord and brain occur in the most different diseases, and therefore have no direct relation to symptoms of paralysis, &c. Anyhow, in progressive paralysis the vessels are for the most

part greatly degenerated, and this not limited to the cord, pyramids, pons, and crura. A review of the twenty-six cases shows that the pyramids are not universally attacked; they were so in only twenty out of twenty-four. The crura cerebri were only found diseased in nine instances, perhaps owing to the difficulty of examination. In the pons, the granule-cells were very irregularly distributed, so that no two sections resembled each other; hence the finding of these bodies here is more chance-work than in the limited pillars of the cord and the medulla oblongata, and this applies still more to the crura cerebri. The fact remains that, under the above mentioned limits as to what progressive paralysis is, there may be always found a disease of the spinal cord, and that disease of the brain can only be proved in a few cases, whilst the intermediate structures between the presumed lesion of the brain and the actual affection of the cord are, as a rule, to some extent diseased.

T. C. SHAW, M.D.

ROSENTHAL ON INVESTIGATIONS ON REFLEX ACTION.—The following results have been obtained by Professor Rosenthal, of Erlangen,

1. From irritation of the entire skin, as well as of exposed nerves, it appears that an appreciable interval is necessary for reflection of the irritation of a sensory nerve to a motor one.

2. This period depends on the strength of the irritation. Leaving, for the moment, out of consideration those irritations which do not excite the maximum reflex action, and comparing only those which just suffice to produce the maximum with still more powerful ones, it appears that the reflex period is shorter the stronger the irritation; and that, when it becomes excessive, the reflex period cannot be estimated.

3. On comparing two symmetrical points on the skin with one another, or on noting the simultaneously-occurring reflex twitches of two symmetrical muscles, there is found a difference of time between the reflex period of one of the skin-points and a muscle placed on the same side, and that of the same skin-spot and a muscle on the other side, the reflex period under the latter circumstances being longer. This difference may be named the 'interval of cross-conduction' (*Zeit der Querleitung*).

4. This 'period of cross-conduction' depends, again, on the strength of the irritation; for whilst it attains its maximum on the application of a certain amount, it disappears completely when the irritation is excessive.

5. 'Reflex period' and 'interval of cross-conduction' are altered by the degree of fatigue of the spinal cord. The former is considerably lengthened, and since the excitability of two symmetrically placed skin-points is not always changed to the same extent, it may so happen that an apparently negative 'interval of cross-conduction' results—i.e., that under certain degrees of strength of irritation, the reflex action from a skin-point on the same side as the muscle begins later than that from the symmetrical skin-point on the other side.

6. If an exposed sensory nerve-trunk be moderately excited in two spots as far distant from each other as possible, the reflex period of the spot more distant from the spinal cord is greater than that of the nearer one. The difference is less the stronger the irritation; not that it can be, therefore, openly avowed that from such experiments only the rapidity of the transmission of excitation in sensory nerves

can be estimated. For such a purpose, experiments should be made with very strong excitants, for by the employment of feeble ones results of little value are obtained, as shown by comparing analogous experiments on motor nerves.

7. With the peripheral motor nerves, dependence of the rapidity of transmission on the strength of excitation cannot be proved. Moderate and excessive degrees of irritation afford similar results. Since, however, a different behaviour of the peripheral sensory nerves is very improbable, one is authorised to conclude that, in the peculiarities noted in sections 2 and 4, there was something special to be attributed to the (ganglionic?) elements of the spinal cord.

8. The nearer an excited spot lies to the spinal cord, the more easily is the reflex period, as regards the 'interval of cross-conduction,' through increase of the strength of the irritation above a moderate quantity diminished. Hence it is possible, with more feeble excitants, to make the interval of cross-conduction imperceptible through two symmetrical points of skin lying near to the spine, than by employing points lying more distant. This behaviour and that under heading 6 receive an explanation from the supposition that, in the peripheral nerves, there is a 'resistance to conduction' which gradually weakens an irritation during its transmission.

In a later communication Rosenthal intends to show how the relations that he has discovered are to be made available for acquiring knowledge of the conditions of excitement in the cord. He says that they agree entirely with the most recent researches upon its structure.

T. C. SHAW.

OBSTETRICS AND GYNÆCOLOGY.

CHIARI ON SULPHATE OF QUININE AS AN ABORTIFACIENT AND OXYTOCIC.—In a lecture reported in the *Gazetta delle Cliniche*, no. 29, 1873, Dr. Chiari, of Milan, says that he has given quinine to forty patients in the Royal St. Catherine Institution of that city, and has arrived at the following results. 1. Disulphate of quinine possesses no action as an abortifacient. 2. In the artificial induction of premature labour, quinine is not to be trusted, either alone or as an adjunct to mechanical means. 3. In cases of languid, suspended, or irregular labour, it would not be sound practice to trust to the action of quinine; and, *à fortiori*, its effect must be regarded as negative when administered in cases of slight malformation of the pelvis. 4. The assertion of Ponti, of Parma, that ergot must give way to Peruvian bark, is chimerical, at least as regards midwifery. 5. When quinine is indicated by the presence of general morbid conditions during pregnancy, it should be given, not only as a remedy for the disease, but also as the best means of preventing abortion or premature labour. 6. Quinine has no power whatever in preventing or modifying morbid conditions of the puerperal state, whether of infectious or of sporadic origin.

A. HENRY, M.D.

PARROT ON THE LOCAL TREATMENT OF GANGRENOUS VULVITIS IN YOUNG GIRLS BY IODOFORM POWDER.—This serious affection is in some cases connected with convalescence from scarlatina, the sequela of a severe attack of fever, or some

similar assemblage of unhealthy conditions affecting the whole of the organism. The younger Guersant and M. Trousseau have given some most useful counsels on this subject. After the indications given by the most powerful modifying agents, these two practitioners have not feared to have recourse to the disorganising action of the actual cautery. This agent has, according to their experience, proved the least uncertain method of circumscribing the limits of the evil. MM. Rilliet and Barthez employed chloride of zinc for the same object, but these means are all very painful, and if, as it is affirmed in the *Progrès Médical*, M. Parrot, the surgeon to the Paris Children's Hospital, has succeeded in avoiding the disagreeable effects of this somewhat barbarous treatment, he will have effected great good. The topical application used at that establishment by the distinguished surgeon in question, is the iodoform powder, which is absolutely painless in use. During several years, M. Parrot has been tolerably successful in his treatment of ulcerated gangrenous vulvitis; combating it by the use of dressings of concentrated solution of chlorate of potash frequently renewed, or cauterisations with nitrate of silver. But neither of these methods, nor others needless to recapitulate, have been so uniformly successful as the iodoform. Iodoform alone, tried as a last resource after other topical applications, generally appeared to arrest the invading progress of ulcer in two or three days, and to rapidly facilitate the appearance of fleshy germs in the bottom of the wound. Iodoform in this case acts in the same way as in chancrous bubos, fungous ulcers, and hospital gangrene. But in order to attain the desired end the iodoform powder must be freely used; not the smallest portion of the wound must remain uncovered by it. When the bottom of the ulceration is very wet and the detritus plentiful, it is advisable to renew the dressing twice a day during the first two days.

The author of the article asserts that he has always very rapidly succeeded in modifying the appearance of these ulcerations by the use of this dressing, and even that he has so completely arrested their progress that none, which have been treated in the way indicated, have exceeded the size of a sixpence. It must also be noticed that this arrest of extension is accompanied by a rapid disappearance of the contiguous cedema, which raises the edges of the ulcerations and gives them a cup-like appearance.

LORAIN ON VAGINAL INJECTION FOLLOWED BY DEATH.—M. Lorain (*Gazette des Hôpitaux*, no. 140, Dec. 1873) has published a remarkable case in which death followed the use, for a girl aged sixteen, suffering from gonorrhoeal vaginitis, of an injection of a small quantity of a weak solution of nitrate of silver into the vagina. The injection was made slowly with a small glass syringe. This was followed by acute pain, considerable elevation of temperature, and vomiting. There was an amelioration of the symptoms for two or three days, but on the fourth day death occurred suddenly. There had been no tympanitis. The necropsy showed suppurative inflammation of the mucous lining of the womb. The Fallopian tubes were infiltrated with pus, and there was pus in the peritoneal cavity with diffuse peritonitis.

M. Lorain cites cases in which the exploration or simple cauterisation of the cervix has caused death, related by Bourdel and Martin, by César, Dolbeau, Béhier, and Letecuturier; with cases of Jobert de

Lamballe, in which cauterisation of the cervix with the hot iron caused death. According to M. Lorain, the injection plays but a small part in the development of these fatal accidents; the penetration of pus from the Fallopian tubes into the peritoneal cavity being explained by the contractile powers of the tubes and the tubo-ovarian nervous excitability caused by pain. Thus, a woman suffering pain and having symptoms of inflammation associated with the tubes and ovaries, is always exposed to considerable danger. The practitioner must, therefore, prohibit her from all exertion and causes of excitement, employ opiates and hypodermic injections to calm pain, prescribe emollient enemata and vaginal injections, then apply bandages or elastic collodion to the belly, and make only such examination as is strictly necessary for diagnosis.

FEHLING ON A CASE OF RUPTURE OF THE VAGINA WITH PROTRUSION OF THE BOWELS.—Dr. F. Fehling (*Archiv für Gynäkologie*, vol. v. part i. 1873) reports a case at the Gynæcological Klinik in Leipzig, occurring in a woman sixty-three years old, mother of thirteen children. Her last pregnancy was a miscarriage. The youngest child was twenty-three years old. All the labours were natural and easy with two exceptions, which happened together. In both instances the forceps were used. The last was thirty years ago; since then, she had always had a falling of the womb. Every kind of pessary had been tried but with no avail. For the last thirteen years, she had ceased to do anything for it. It invariably came down on standing, sitting, or walking, forming a tumour about the size of a child's head. When she lay down, it went up without any assistance. Whenever it caused her any inconvenience, she was in the habit of reducing it with her fingers. Whilst she was ascending the steps of the village well with a weight on her back, the womb prolapsed. She hastily endeavoured to replace it with her fingers, using considerable force. She felt something give way, and immediately the bowels protruded.

Dr. Fehling was summoned eight hours after the accident, and found the woman in a state of collapse, with the small intestines protruding from the vulva, forming a mass as large as a man's head. The intestines were cool to the touch, showed no signs of peristaltic movement, and were of a purple colour. Putting the woman slightly under the influence of chloroform, he tried to replace the bowels, which he succeeded in doing, but could not retain them in position, from want, as it seemed to him, of sufficient room for so large a mass in the abdominal cavity. A second effort was made, the patient being placed on her knees and elbows, and completely anaesthetised, but with no better result. The woman rapidly sank, and died eleven hours after the accident of shock. The *post mortem* examination showed a great increase of omental fat and a thinning of the vaginal walls.

The author states that he believes this to be an unique case, as he finds no report of any instance of ruptured vagina under such circumstances; it shows how easily the vaginal walls may be torn in a case of prolapsus uteri of long duration. In all such cases, care should be used in reducing the prolapse. He also thinks the inability to keep the intestines in position when replaced, arose from the capacity of the abdomen being diminished through the long-standing prolapsus uteri.

W. C. GRIGG, M.D.

SPIEGELBERG ON PRIMARY AND ISOLATED CARCINOMA OF THE BODY OF THE UTERUS.—Professor Spiegelberg (*Archiv für Gynäkologie*, vol. vi. part i.) relates a case where there was distinction of the posterior wall and fundus, and enucleation of the cancer mass. It occurred in a woman forty-nine years old, sterile; she had menstruated regularly up to forty-five. During the last year, she had been subject to a continuous bloody discharge. With its appearance she became affected with severe pains, more intense at night. On examination in October, 1872, the body of the uterus was found uniformly, but not very considerably enlarged, and retroflexed; it could not be redressed, and was very tender to the touch. The cervix was long, and did not participate in the swelling. The cervical canal was narrow, and discharged a profuse purulent secretion. An intra-uterine growth being suspected, an attempt was made to dilate the cervix with laminaria and spongetents, but the internal os opposite where the flexion was would not yield. It gave rise to great pain. Hypodermic injections of ergotine were used for eight days, and had the effect of making the uterus harder and shortening the cervix. In January, 1873, the patient being worse, she was again examined. The discharge was less, but ichorous and offensive. The uterus was still retroflexed, the under surface enlarged, and the cervix shortened. This being regarded as an indication of the descent of the supposed tumour, the cervix was rapidly dilated with spongetents. On making a digital examination, the posterior internal surface of the uterus was found diffusely infiltrated and covered with friable masses, extending upwards to the anterior surface.

As far as possible the whole of these masses, which filled about the hollow of the hand, were removed with the curette. The hæmorrhage was trifling, and the reaction slight. The pain and discharge ceased, and the patient improved rapidly. This operation was performed on February 8th. The pain having returned on the 24th, the cervix was again rapidly and thoroughly dilated, and projections and unevennesses were again scratched off. The elevations had extended more to the upper and left surfaces with intermediate ulcerated spaces. The bleeding was slight. Soon afterwards the patient collapsed and died the next day, with symptoms of peritonitis from perforation.

The *post mortem* examination showed extensive purulent peritonitis. The posterior surface of the uterus and the fundus were firmly adherent to the bottom of Douglas's pouch and the anterior wall of the rectum, completely obliterating the Douglas's pouch. The sigmoid flexure with its mesentery were attached to the anterior surface, and opposite the point of attachment there was a small opening communicating between the cavity of the uterus and the abdomen. The cervix was healthy; the anterior wall was infiltrated with pale yellow-coloured medullary masses.

The posterior wall, together with the cervix, only measured between one and a-half to two inches in height. The rest, with the fundus, was gone. An examination with the microscope by Prof. Cohnheim showed the carcinomatous character of the infiltration.

There can be no doubt that the operation was the immediate cause of death. The diagnosis upon which it was performed proved to be correct, viz., that it was epithelioma, and consequently the operation was justifiable.

W. C. GRIGG, M.D.

RANSE ON AN INTERESTING CASE OF VESICO-VAGINAL FISTULA.—Ranse (*Vierteljahrsschrift für die Praktische Heilkunde*, vol. xxxi., 1874) relates a case occurring in a lady after a severe confinement. The urine continued for about six months to issue *per vaginam*, and then suddenly, without any operation, ceased. After that, the catamenia came with the urine for eight years. She then underwent an examination by Ganeau, who found complete atresia vaginæ; in eight days, by means of a lithotome caché and sponge-tents, he succeeded in dilating the vagina; the vaginal portion of the cervix was made out to be quite free, except the anterior lip, which had become grown to the inner surface of the bladder. He operated with success. Within ten months afterwards she gave birth to a child, which was followed by considerable *post partum* hæmorrhage, requiring the passing of the hand to arrest it. Again she was troubled with a vesico-vaginal fistula, and underwent another operation by Nélaton, but the fistula was not entirely closed. Again, after a lapse of eight years, she consulted Ganeau, who found, a short distance from the cervix, a small opening, which he successfully closed. After that, she could never retain her urine longer than an hour, when it would run away. Ganeau could not account for it, and as all medical means failed, he ordered an air-pessary, by which means she was able to retain her urine for two hours and more.

W. C. GRIGG, M.D.

CLEMENS ON PRURITUS URETHRÆ AND PRURITUS VAGINÆ.—H. Clemens (*Praktische Heilkunde*, vol. i. 1874) treats this obstinate affection by means of grooved metal bougies smeared with an ointment containing borax and lard in the proportions of 1 to 3. Should he not succeed by this means, he uses the induced current of electricity by passing a leaden bougie, smeared with the above preparation, into the bladder, to which he attaches one pole, while the other pole is applied to the nape of the neck; a gentle current of induced electricity is transmitted for about ten minutes at a time. In pruritus vaginæ he passes one pole, with a sponge at the end, up the vagina, smeared with borax. He states that by this means he has cured the most inveterate cases in old women, and has also cured cases of chorea magna, where it was dependent upon hyperæsthesia of the urethral mucous membrane.

W. C. GRIGG, M.D.

REVIEWS.

On Food; Its Varieties, Composition, Nutritive Value, Comparative Digestibility, Physiological Functions and Uses, Preparation, Culinary Treatment, Preservation, Adulteration, &c. By H. LETHEBY, M.B., M.A., &c. Second edition.

The four Cantor lectures delivered before the Society of Arts in 1868 gave the author an excellent opportunity of dealing with the wide subject of the economy of food, and afterwards of utilising his large experience in the form of the present work. The task has been performed in a manner very acceptable to the public. Other popular works on food have also recently made their appearance; among them are the lectures on food delivered some years since by Dr. Lankester, when superintendent of the animal products and food collections of the Kensington Museum, located chiefly now at Bethnal Green.

Foods, by Dr. E. Smith, is also a re-issue of his work on practical dietary, treating food topics in very popular manner. The whole subject is large and deeply interesting, including as it does diet and the construction of dietaries fit to meet the requirements and conditions of civilised life, and we naturally seek to have placed before us all that is known on the nature and quality of articles capable of being prepared for food, whether they are of vegetable or animal origin. Dr. Letheby is highly qualified, and has well fulfilled this demand.

The nutritive qualities of different articles of food, how they can best be distributed and utilised with maximum effect upon the individual, occupy the first pages of Dr. Letheby's first lecture. Quoting from Dr. E. Smith, he fixes the amount of 4,100 grains of carbon-food, and 190 grains of nitrogen-food as the normal proportion of a barely sustaining diet for an adult.

This is known to tally with the carbon and nitrogen exhaled and secreted from the body in health and idleness.

All the various kinds of vegetable and animal foods then come under his consideration, and are compared with each other, and with the above standard. The saline or mineral foods are not lost sight of in the place they occupy in the animal economy.

Before leaving this part of the subject, he adverts to the food-supply of the metropolis, which, as he says, goes on with the regularity and precision of a machine, without government or even municipal interference, but simply through the magical power and unfettered action of free trade.

In treating of the digestibility of food, the function of nitrogenous food, the sources of muscular power, the action of fatty, starch, sugar, and saline matters, the development of heat and other modes of motion and manifestations of force, Dr. Letheby takes into account the experience of every modern physiologist, tending as it does to shake the generalisations of Liebig with regard to the quantity of azotised food needful to restore the wear and tear of metamorphosed tissue.

He must have added immensely to the lecture since it was delivered, on diet and the construction of dietaries. Some experience which has been gained from the siege of Paris is here recorded. At that perilous time, the French Government consulted the leading physicians in the city, and instructed Dr. Sée to lecture on the subject of food and dietary. It was then necessary to make attempts to maintain life with a minimum food-supply. A diet with a daily ration equal to only 94 grains of nitrogen and 2,234 grains of carbon was tried, and it was found that that amount would not sustain life, even when the body was performing no work beyond its own physiological movements. The consequences of low feeding, the effects of famine, dietaries for children, for the poor in workhouses, for prisoners, &c., are all thoroughly treated by Dr. Letheby in his third lecture.

It is of great public importance to study every method, and to find out, if possible, new and better methods of preserving food. Our naval authorities appeal to science to supplant the unwholesome junk beef of our navy and mercantile service, by some other more palatable means of preservation. The Society of Arts offers a prize for a simple and effectual means for supplying our markets with fresh meat, either from the colonies or

from South America, where, it appears, in the latter a bullock costs but 3*l*. and legs of mutton can be bought for 3*s*. a dozen.

Dr. Letheby has given full consideration to this subject, and has devoted to it several pages of his work, which are well deserving of perusal by cattle-dealers and merchants, as well as by chemists and patentees, whose intelligence is now eagerly directed to the question of food-importation as a new branch of industrial enterprise.

It is rather singular that, on the subject of 'fraudulent sophistications of food,' a subject at present extremely popular, Dr. Letheby should have been so sparing of his remarks; for a very few pages only are devoted to food-adulteration, and the Adulteration of Food Acts of 1860 and the amended one of 1872, which latter must have been in a preparatory stage for passing into law, and its provisions well known to him, have been scarcely alluded to.

It is but fair to say that this is the only weak point we can discover in his otherwise excellent book.

The author candidly says that he has only briefly adverted to the principal food adulterations; but when we consider his capabilities for such an undertaking, and knowing his early labours in this field of research, it is to be regretted that he could not have found time to embody in this part of his lectures his experience in food-analysis, and make it equally valuable with the rest of the book for those who desire to refer to it.

The numerous tables and calculations, made in accordance with modern analytical data, extending as they do into all branches of chemical and physiological research, are most valuable to working students and every one engaged in food-analysis; while, as a popular exposition of the varieties of food, their nutritive values, and how they may best be utilised profitably to individuals or to the nation, the work of Dr. Letheby stands far above anything of the kind hitherto presented to the public.

W. H. HARDWICKE, M.D.

Clinical Researches in Electro-Surgery. By A. D. ROCKWELL, M.D., and GEORGE M. BEARD, M.D. pp. 72. New York: 1873.

Lectures on the Clinical Uses of Electricity. By WALTER G. SMITH, M.D., Assistant Physician to the Adelaide Hospital. pp. 51. Dublin: 1873.

Lectures on the Clinical Uses of Electricity, delivered in University College Hospital. By J. RUSSELL REYNOLDS, M.D., F.R.S., Physician to University College Hospital. Second Edition, pp. 116. London: 1873.

The last-named of these three books on electricity is already so favourably known to the profession, that it is not necessary to say more than that the second edition, which is somewhat enlarged, fully sustains the reputation acquired by the first. Dr. Walter Smith's lectures to the Dublin students on the same subject are very good, as far as they go, but the principle of condensation has in them been carried to the furthest limit. A considerable number of very important facts has been altogether omitted; and we should advise Dr. Smith, if his little book were to reach a second edition, to enlarge it so as to become at least twice the size of the present one.

Drs. Beard and Rockwell have recorded a number of cases of various kinds of tumours treated by electrolysis, with the same candour which has

favourably characterised their previous writings. Among the successful cases are some of nævus, goitre, and epithelioma. Their experience in the electrolytic treatment of scirrhus confirms the result arrived at by ourselves, viz., that electrolysis is most effective in relieving the pain of the cancer, but powerless to destroy the tumour altogether, or to prevent its recurrence or secondary deposits. Nef-tel's far more favourable results with the electrolytic treatment of cancer are at present not corroborated by other observers. The second chapter in Drs. Beard and Rockwell's little book treats of the results of galvanisation in certain diseases of the skin. They use what they call central galvanisation; i.e. an application of the anode to the head, neck and spine, and of the cathode to the epigastrium, for about ten minutes at a time; and they think this proceeding preferable to an application to the diseased surface. They describe, amongst others, a case of severe and obstinate chronic eczema of the leg, of eight years' standing, accompanied with intolerable itching, where various remedies had failed, and where rapid relief and a permanent cure followed the treatment by central galvanisation; also cases of acne, prurigo, psoriasis, and pityriasis, which were beneficially affected. There being now such a superabundance of special skin-hospitals, and departments for skin-diseases in general hospitals, we are surprised that not one of their zealous medical superintendents has as yet thought of testing the accuracy of these American observations in practice, the present publication being by no means the first on the subject.

JULIUS ALTHAUS, M.D.

MISCELLANY.

DR. KUNDRATH, assistant to Professor Rokitsansky, has been invited to the professorship of Pathological Anatomy, in the University of Gießen.

THE WINES OF FRANCE.—During the last few days 300 barrels of adulterated wine were thrown into the Seine, by order of the judicial authorities. It contained, with a little alcohol or wine, which was even wanting in some of the barrels, water, carmine, cochineal, tincture of logwood, sulphate of alumina, potass, aniline, fuch-sine, &c.

THE PROPAGATION OF CHOLERA.—The official report of Dr. Hirsch, just published by the German Government, on the appearance and march of the cholera in the Prussian provinces of Posen and Prussia in 1873, supports the conclusions established by British and Indian observers, that the cholera is carried along the lines of human communication. The experience of late years has proved that the disease is imported almost regularly by the barks on the Vistula, the wood-rafts, and the cargoes of wheat. The author shows by a series of carefully investigated facts, that the cholera advanced into Posen and Prussia along the course which the wood-trains pursue, and followed in their track. He dwells upon the necessity of public hygiene.

TRANSFUSION OF BLOOD.—Dr. Leared writes to us as follows. Will you allow me to point out that transfusion of blood as a remedy in case of snake-bites, spoken of in your review of Drs. Brunton and Fayer's paper read lately at the Royal Society as having been proposed by these gentlemen, is not a new idea. The same suggestion was made many years ago by Dr. Cockle in his *Essay on the Poison of the Cobra di Capello* (London. 1852). He says at page 27, 'There yet remains one

mode of treatment to propose, and I do so with diffidence, from the known gravity of the operation, and the difficulty attending its performance, and only under a deep conviction (from what I have witnessed in some experiments relating to poisons), that it may be justifiably adopted under the desperate circumstances of these cases. I allude to the transfusion of blood, and would suggest a trial of it in that stage which is characterised by livid face with stertor, free blood-letting being first premised.'

CREMATION.—At a recent meeting of the Vienna Society of Medicine, a committee was nominated to consider the subject of cremation of the body, a question which for a long time has been agitated in Germany, and has been revived, *à propos* of the translation of Sir Henry Thompson's paper by Dr. Koepl. Serious objections are raised against the realisation of this idea, the practical execution of which would also present difficulties. It is not proposed to render cremation obligatory, but simply practicable. Dr. Kohn read a letter from the burgomaster and some members of the Common Council of Oderdoerling, who consented to leave their bodies, by will, to be burned, if the measure were compatible with the law. From the sanitary point of view there are no objections; at least, so thought the majority of the meeting. Dr. Schnitzler, however, remarked that in India, where combustion is often employed, the air is sometimes infected for many miles round. Chemistry must be looked to for a means of disposing of the decomposing matters innocuously. The society thought that the question ought to be studied deeply before it could pronounce an opinion, and decide on its course of action. Hence, the necessity of the nomination of a special committee. In England the matter has already gone further; by the use of a Siemens' furnace, Sir Henry Thompson has shown that it is possible to procure complete combustion without any atmospheric infection, and a Cremation Society has been formed, of which Mr. Eassie, C.E., is the secretary, *pro tem.*, and which has put forward the following declaration, to which signatures are invited:—

'We, the undersigned, disapprove the present custom of burying the dead; and we desire to substitute some

mode which shall rapidly resolve the body into its component elements by a process which cannot offend the living, and shall render the remains perfectly innocuous. Until some better method is devised, we desire to adopt that usually known as cremation.'

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, APRIL 8, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

THE SIGNS OF DEATH.*

The most important prizes which the Academy of Sciences in Paris had to award in 1873 were those founded by the Marquis d'Ourches, in reference to premature interments. They were equally important both from the nature of the question and from the number of works sent in competition, amounting to no fewer than 102, not including a dozen which arrived too late. The principal of these prizes consisted of a sum of 20,000 francs (800*l.*), to be awarded for the discovery of a simple and popular method of recognising the signs of real death in a certain and indubitable manner; to quote the terms of the Marquis's will, 'a method which may be put into practice by poor uneducated villagers.' The other prize of 5,000 francs (200*l.*) is to be awarded for the discovery of a scientific method of recognising with certainty the signs of actual death.

A hundred years ago M. Bruhier published a truly horrifying list of fifteen persons buried alive, four opened before they were dead, and a hundred and three falsely reported to be dead, of whom the majority came back to life before interment actually took place. This list was prepared to impress the public mind with the necessity for a general legislative enactment on interments and embalmings; but the statements contained in it are utterly devoid of authenticity. Doubtless Bruhier thought that in forensic medicine, as on the stage, it is better to produce a sensation than to pay too much attention to truth; and Louis, the secretary of the old Academy of Surgery, had no difficulty in showing the exaggerations and errors of this lamentable catalogue in his *Lettres sur la Certitude des Signes de la Mort*. All these phantoms, evoked by the gloomy imagination of the credulous physician, vanish when closely looked at in a critical light, as the bad dreams of a disturbed night disperse at the first beams of daylight.

This grave question of apparent death and premature inhumation is one of great antiquity, and the involuntary terror which clings to it has perpetuated itself through ages, from generations who were ignorant to the present generation, which ought to be enlightened; and thus the fables transmitted by preceding ages have come down to us. Pliny has written an entire volume on what were supposed to be corpses who were awakened by the noise of shouting or during the funeral ceremonies. Many, according to this author, were recalled to life by the flames of the funeral pyre, from which they could

not be removed with sufficient rapidity; amongst them being many exalted personages—prætors, consuls, who 'ex ipsis elati rediere sepulchris.'

But how is it possible to accept in good faith these miraculous incidents of resurrection related by the ancient authors, and repeated in later times? Here it is Asclepiades who, meeting a corpse, has the procession stopped, the torches extinguished, and recalls the defunct to life in the presence of the astonished and greatly afflicted heirs. There, a certain Aufidius has a timely escape from the flames of the funeral pyre. He pays the undertaker without haggling over it, but revenges himself on that functionary by attending his funeral at a subsequent period. Again, a Roman matron, prematurely devoted to the funeral pyre, became a mother during the obsequies in such a manner, says Valerius Maximus, 'that a mother was delivered after her death, and a child was carried to the grave before having been born.'

Many other more modern and famous examples have no more foundation, beginning with the history of the celebrated François Cville, a Norman, or more probably Gascon captain, who in the reign of Charles IX. described himself as 'three times dead, three times buried, and three times resuscitated by the grace of God.' It is by no means true that the profession have made cruel mistakes with regard to persons apparently dead. One chronicle relates that Vesalius, the creator of anatomy, the chief surgeon to Charles V. and Philip II., raised his scalpel on the body of a still living man, and was in consequence condemned to death, and as a commutation of his sentence sent into exile in the Holy Land. Thus is history written. We search in vain in the contemporary writers for this fact relating to Vesalius. The necropsy, the condemnation to capital punishment, are equally pure inventions; and if Vesalius did go to Palestine, it was only as a voyage undertaken for the benefit of his health. In Bouillet's dictionary, we are told that the Abbé Prevôt, having fallen down insensible in the forest of Chantilly, expired under the knife of a village practitioner, charged with the judicial necropsy. At the first stroke of the scalpel the author of *Manon Lescaut* uttered a cry, and died this time without any mistake. But a rigorous inquest proved the falsity of this anticipated necropsy, and of that much deplored tragic death. The celebrated author of *Manon Lescaut* died of apoplexy, perhaps even of indigestion, after leaving a dinner with the Benedictines. The anatomist Winslow, a Lutheran converted to Catholicism by Bossuet, and who had the good luck (as Voltaire has said of Pelisson) to become enlightened, and to change his religion at a time when this change was likely to lead him to dignity and fortune—Winslow, the author of a dissertation on the uncertainty of the signs of death, introduced this phrase into his memoir: 'Have I not myself been twice condemned by the physicians to be interred (ferali addictum involucro), the first time in my childhood and the second in my youth?' But it is somewhat singular, that notwithstanding this declaration, the biographers of Winslow have entirely passed over in silence this double interment. According to the very just remark of a distinguished medical legist, when one has had the good fortune to have been twice interred without great damage, even with profit, for this example of resuscitation lived to be more than nonagenarian, and loaded with years and honours, very precise and circumstantial details of so strange an adventure are due; and it does not

* Report on the prizes founded by the Marquis d'Ourches for the discovery of a simple and popular means of recognising the signs of death.

suffice to say in a lively tone and in a careless manner: 'I have been twice interred during my youth.' One startling fact, however, in the history of these wrongfully interred personages is, that the earth lay lightly on them. Bruhier gives the case of one who lived thirty-two years after his apparent decease; another lived forty-two years, and subsequently became the father of seven children; a third lived fifty-three years, and, what is still more extraordinary, he was resuscitated after having lain underground during seven weeks. Several women likewise lived many years their second lease of life, and again became mothers.

About fifty years ago, a young preacher was attacked by syncope in the pulpit, and this syncope lasted so long that the patient heard the words of the doctor who, rather hastily according to our ideas, gave the certificate of interment for the next day, and also his bishop reciting the *De profundis* at his side. The dimensions of the coffin were taken, we are told, but towards the evening a friendly voice dispelled this dangerous sleep in time, and the next day the preacher reappeared in his pulpit. At a future period, he became a cardinal, and senator of the Second Empire, and forty years afterwards used to agitate his colleagues by the true recital of the peril he had encountered.

In our days, the examples of premature interment, so frequent in former days, have become more and more rare. If we find one from time to time in the public prints, its authenticity is open to contest; however, as soon as the authorities, in order to quiet the emotion aroused in some feeble minds by these dreary narrations, take it upon themselves to verify the fact officially, nothing of it remains, and the miracle disappears before the realities of a well drawn-up official statement.

According to the historical standard, then, the fear of premature inhumation is chimerical, and yet it is deeply rooted in many minds, in the highest as in the lowest classes of society. This fear is reproduced in Molière's couplet:

'Qui tôt ensevelit bien souvent assassine,
Et tel est cru défunt, qui n'en a que la mine.'

It is also expressed in a very forcible manner in a speech delivered in the French senate some years since, on the subject of a petition in which more rigorous preventive measures were demanded from the legislature.

'Every one of us,' said the speaker, 'has felt his pity aroused by the thought that it was possible that a man might be immured alive in a coffin. Reason itself is unsettled at the idea of that horrible struggle of an unhappy being who wakes up to find himself buried, who is resuscitated for an instant, only to succumb to the tortures of the most frightful torment ever invented by the most cruel barbarity. The grave has repeated to us the horror of these fearful dramas; in turning over old cemeteries, skeletons have been found in the coffins drawn into attitudes of the greatest desperation, the fearful contractions of the limbs betraying the last struggles for existence; the anguish of a fearful agony of which not a cry nor a groan could be heard by the living.' Certainly the filling up of this picture is masterly. It made the senators shudder; but after all it is but a literary development. If even mistakes which are now impossible with the strict observation of mortuary legislation, if fatal mistakes have really taken place, as, for instance, at the time of the great plagues, they may be im-

puted to ignorance and to the excessive haste of the people about the deceased. Medical science, whose business it is to distinguish between death and life, cannot be responsible for these errors (behind which crime sometimes conceals itself).

Besides, popular prejudices are the offspring of ignorance, and it is the province of science to destroy or at least to combat them. On what pseudo-scientific data does the fear of being buried alive rest? On the belief shared by some medical men that diseases are frequently met with, such as catalepsy and lethargy, in which death is perfectly simulated. But the facts of catalepsy (not to speak of some slight cataleptic phenomena) are so rare that even the existence of that affection may be legitimately doubted, and, *à fortiori*, the same remark may be applied to cases of lethargy. Clinical medicine often shows us certain pathological sleeps which are more or less profound, and which to inexperienced eyes may appear akin to death. But medical science ought to proclaim, so loudly that the most deaf can hear, that there is never any abolition of circulation or respiration in these cataleptic and lethargic conditions; the pulsation of the heart, the pulse, the respiratory movement are always evident; that is to say, the most positive signs of life remain manifest. Lethargy, such as it is understood and dreaded by the public, such as it has been described by ancient authors, has no existence. One of the characters in Reynard's *Légataire Universel*, exclaims—

'Quelles friponneries !

Je suis las à la fin de tant de léthargies ;'

and every serious physician will, I think, be of the same opinion as the dramatist. [The reporter says that in these preliminary remarks, the opinions expressed are purely personal, and do not compromise any one but himself, but he could not dispense with laying them before the Academy to justify his incredulity, with regard to subterranean resurrections, which age, experience, and reflection have only tended to confirm. In these peculiar miraculous matters, which are so attractive to minds having a taste for the mysterious, truth can only be eliminated by the aid of the crucible of scepticism.]

Wherefore then speak of the uncertainty of the signs of death? Certainly the phrase was not without appropriateness in the times of universal ignorance, when medicine was not as yet and could not be anything but a confused mass of conjectures; but it would be unjust now that, receiving inspiration from the progress of the physical sciences and appropriating their conquests to itself, medicine makes efforts to raise itself to the level of the exact sciences. Certainty is the term which should be made use of at the present time. The Academy has heard, and every medical man should read, the very conscientious report in which M. Devergie comments on the paper sent in to the Commission, in which he treats in a masterly manner of all the scientific and administrative questions which form part of the subject of inhumation. What does this expert show us, through the caution which a physician so well qualified in forensic as in general medicine is obliged to impose on himself? To what conclusion does M. Devergie come? To the conclusion that modern science possesses a large number of certain signs of death.

Two signs of death are derived from the stoppage of the circulation in the capillary vessels. The first of these signs consists in this: that if we apply cupping glasses to the pit of the stomach after the heart

has ceased to beat, the skin, still susceptible of being congested, gives out blood under the blade of the scarificator; while later on, the skin, henceforth dead, no longer bleeds if we again apply the scarificator. M. Levasseur, physician to the Hôtel-Dieu at Rouen, has carefully studied this phenomenon by the help of numerous experiments; and the Academy confers on him an honourable mention.

The second sign consists in the modifications presented by the burning of the pulp of the finger in the flame of a candle. According to M. Martenot, of Cordova, to whom the commission grants a reward of 500 francs, this burning produces blisters which will be filled with serous matter if life still continue, and will only contain vapour if life be extinct.

It has been said that the eye is the mirror of the soul. It might with more justice be said to be the mirror of death. Indeed, Louis had already in his time indicated the subsidence and the relaxation of the eyes as a sign of the extinction of life; and Winslow had likewise described the glairy coat, the species of veil which seems to spread itself before the cornea in dying persons (*nataantia lumina*). It has also been observed in the present day, that belladonna, which, during life dilates the pupil, and the Calabar bean, which contracts it, have no action on the iris some hours after death. Dr. Larcher, of Passy, has discovered a new and certain sign of death, the grey and cloudy spot which first appears on the external portion of the sclerotic, and at last takes entire possession of it. Here a phenomenon of local decomposition is in question, preceding general decomposition by many hours. M. Larcher's observations on this point relate to nearly nine hundred subjects, and a reward of 500 francs has been awarded to him. Another equally positive and much more rapid sign is the general discolouration of the back of the eye, which, looked at through the ophthalmoscope, appears of a deep red colour during life, and becomes pale and of a yellowish white at the moment of death. M. Poncet, a military surgeon, who has already gained a Godard prize, is honourably mentioned for his memoir, in which these ophthalmoscopic researches are made known.

The value of electricity in forensic medicine, is founded on the persistence of muscular contractility during the first hours only following death. Nysten and Hallé had already proved that loss of electric contractility is a certain sign of death. M. Duchenne de Boulogne placed very fine needles in the muscles, passed currents from the induction coil through them, fifteen to twenty hours after the presumed death, and never under these conditions saw the least motion in the needles. The academical commission grants an honourable mention to M. Crimose for his persevering efforts in the application of electric dynamics in the verification of death, and in the construction of more practical instruments.

The memoir of one of the winners of a prize, M. Molland, appears, according to M. Devergie, to be less an original work than numerical conclusions on the comparative value of all the signs of death known to science. The writer, who is attached to the office for verification of deaths in the city of Paris, has made his observations on more than fifteen thousand subjects, which he inspected several times, so as to verify the succession of the phenomena of the extinction of life. His attention was particularly directed to the violet-coloured spots which in the dead body showed themselves on the dependent part. He traced them to their origin and through their

evolution, and he has arrived at the conclusion that these cadaveric livid appearances are a constant characteristic of death, since they have never failed to be present in his fifteen thousand observations. This sign is of so much the more practical value that it generally appears shortly after death, and therefore the commission have awarded to M. Molland, hospital surgeon of Paris, a premium of 2,000 francs.

(To be continued.)

FRENCH AFFAIRS.

(From a French Correspondent.)

I see without surprise, and even with some pleasure, that my protests against the egotism and ignorance of foreign science which lie at the root of the present decadence of modern French medical science, as of so much else that has shown decadence in our country, have awakened some angry remonstrance here. I wish from my heart that they could always be as well considered and as indignantly answered as my last letter was, by a very accomplished *agrégé* of the French faculty in our most serious medical journal, the *Gazette Hebdomadaire*. As M. Hénocque gives up M. Garnier to European reprobation, and only protests for himself that the experiments of Ferrier, &c. have not been ignored in that journal, I shall willingly pass over his clever reply, and content myself with the hope that he will join me in enforcing an attention to one of the first laws of scientific progress, which he admits equally with myself. That law is, that the man of science shall profit by the illumination of cosmopolitan intelligence, instead of working with his head in a (French) bush, outside of which he can see and hear nothing, and whence he catches the distant echoes of the din in the world's workshops only to ridicule or to abuse the feeble impressions so conveyed to him.

As an example of the spirit which I deprecate, let me quote one passage from a book by an eminent compatriot, just issued from the press. M. Gallard, author of *Leçons Cliniques sur les Maladies des Femmes*, is a physician of the Hôpital de la Pitié, an officer of the Legion of Honour, and holds a high place among us. He is discussing the treatment of chronic metritis by sea-baths, which he considers very efficacious, but which are objected to by Virchow and Scanzoni. 'It might seem surprising,' he says, 'to find these two learned physiologists thus stop short at the first part of the phenomenon (temporary revulsion of blood from the periphery to the interior), without taking into account the second (the period of reaction), which is certainly the most important, if we did not see the motive of this aberration in the desire (very natural with Germans, who are always calculating) to prescribe cold affusion and sea-baths, which they condemn. Our Prussian colleagues have indeed perfectly understood that, if sea-baths are recognised as useful, it is not to the shores of the Baltic or the North Sea that patients will prefer to go to take them, and that is why they have decided that they must be hurtful.' One might have been content to treat this singularly outrageous mode of discussing a scientific question as itself a temporary aberration, but that the whole book breathes the spirit of ultra-exclusiveness, and that it is in consequence twenty years behind European therapeutics, and that a

critic in a very able journal, the *Bulletin de Thérapeutique*, picks out this passage which I had marked with notes of admiration, for sincere eulogy. He desires to benefit his readers by calling their attention to the able 'psychological diagnosis of the honest and calm physician of the Pitié.' When a French author of eminence can be found to pen such a judgment, and a critic of repute to eulogise it, my function of censorship, to which M. Hénocque takes exception, cannot in my opinion be deemed useless to my countrymen. It will not, after this, surprise your readers to learn that for M. Gallard the works of Barnes, Simpson, and Sims, which mark epochs in obstetrical practice, might as well not have been written: that he prefers in practice Ricord and Cusco's speculum, has little to say to Sims's, that the pessaries which he recommends are such as have long been superseded by every other country, that his methods of dilatation of the cervix, and of treatment of polypi and of granulations, are equally old-fashioned, and that the whole book is written as if French obstetric science occupied a lofty pinnacle of solitary glory in the educated universe.

It was in this spirit that our friend M. Garnier observes in his former review of medical progress of 1874 (in which you will not find any but a French name mentioned), when speaking of the discoveries of M. Ranvier and M. Vulpian, that these are 'things which will disquiet the Germans.' The Bismarck spectre needs to be exorcised from our laboratories and our hospitals.

WILKS ON THE PHYSICAL EXAMINATION OF THE CHEST.*

(Continued from page 191.)

Percussion.—This is by far the most difficult part of physical diagnosis, because there is no universal agreement as to the true conditions which produce the various sounds, and there is no exact definition given to the terms which are used; moreover, many writers adopt expressions of their own selection, which cannot be accurately interpreted by the reader. For instance, it is impossible to define it, or to convey in any words to you what I myself understand by the common term 'resonance;' and the same, though to a less extent, is the case with the word 'dull;' but when we read in books of such expressions as 'empty' and 'full,' the words often convey no meaning at all. I do not find fault with the attempt to give names, for it is evident that, under varying conditions, different sounds must be elicited by striking the chest; but since, at the present time, we are not all agreed as to the true causes producing them, it is impossible to use expressions which are intelligible to all. I say there is no general agreement as to how the sounds are produced, some maintaining with Piorry (who has written a poem on Percussion) that every part of the body gives out its own note on percussion, whilst others, with Bennett, have been content to teach that there are three main sounds, according as we percuss over a solid, a liquid, or air; these would be illustrated by striking over the liver, bladder, or stomach, and therefore might be styled respectively parenchymatous, humoral, and tympanitic sounds. Without systematising too much, we are generally content

to say that we elicit from the walls of the chest a given sound which varies with the condition of the ribs and their covering, but more especially according to the nature of the contents within. The sound is really produced by a vibration of the ribs which can be felt by the finger, and the note varies more especially with the contents. I have no doubt that the subject might be taken up advantageously as a simple question of acoustics, and then appropriate terms might be given. You will see on a moment's thought, that the nature of the object struck must determine a difference in the note, as also whether it be solid or hollow; the sound again varying with the character of the contents.

When one considers that percussion of an object is a simple physical method of ascertaining what is within, it is remarkable that its practice has been left to modern times; we know, if we knock at the door of an empty room, that the hollow sound produced will tell us of its condition, just as we know by striking a barrel whether it be empty or full; in the same way the builder knows by striking a wall whether it be composed of brick or lath and plaster; and when we stop on our journey at the railway station, a man comes and knocks the wheels in order to discover a flaw. One of the most remarkable illustrations of the information to be obtained by percussion occurs in *The Mystery of Edwin Drood*, the novel which Dickens had in hand when death suddenly disarmed him of his pen. It would be most interesting to know whether he gained the idea from observing the methods used amongst us medical men, or whether, quite irrespectively of us, he had merely in a fanciful and somewhat exaggerated manner described what he had actually seen performed amongst workmen. The passage is sufficiently interesting to read to you, if it be only to show how percussion is merely a matter of physics.

'Is there anything new down in the crypt, Durdles?' asks John Jasper.

'There's an old 'un under the seventh pillar on the left as you go down the broken steps of the little underground chapel. Now, lookee here. You pitch your note, don't you, Mr. Jasper?'

'Yes.'

'So I sound for mine. I take my hammer and I tap. (Here he strikes the pavement.) I tap, tap, tap. Solid! I go on tapping. Solid still! Tap again. Holloa! hollow. Tap again, persevering. Solid in hollow! Tap, tap, tap, to try it better. Solid in hollow; and inside solid, hollow again! There you are! Old 'un crumbled away in stone coffin in vault.'

'Astonishing.'

To simplify the matter as much as possible, I shall merely describe to you the four most striking different conditions in which the chest may be placed in health and disease, and which will correspond in the main to the solid liquid and gaseous already mentioned. The chest may be full of air or full of liquid, or of solid hepatised lung, or, fourthly, of the natural lung. The sounds elicited by striking the chest under these different circumstances can be imitated by taking four boxes and filling them respectively with air, water, wood, or wool. If we made a chest empty by removing the lungs, and filled the one side with air and the other with water, we should have two very different sounds produced upon striking them. If we percussed the one side it would sound like a drum, and we should have no doubt that it was hollow, and we should call the sound tympanic.

* *Guy's Hospital Gazette*, March 14.

If we struck the other side, we should elicit no sound whatever; no vibration would occur in the ribs, and therefore no note. This would be called dulness on percussion, or perhaps a better term than dulness would be tonelessness; it would be as toneless as striking the thigh. Now, if we took another chest and placed within it some wool or spongy lung; we should have necessarily an intermediate sound; we should not have the hollow sound of simple air, nor the total want of vibration as in the case of fluid, but another note would be produced. This note, produced by striking over a healthy lung, is called natural resonance. I cannot describe it to you in so many words, but you must familiarise your ears to the note, and then you will take it as a standard; any sound above it is called hyperresonant, as you have in an emphysematous lung, which increases until you reach the tympanic note, and anything below it implies the existence of more solid material within, until perfect dulness is reached.

Now the greatest difficulty in the explanation of a note exists in the case where a solid fills the chest, as when a piece of wood should have been introduced, or when, in the living subject, the lung is hepatised. You will see that dulness corresponds to tonelessness, and this very often means the non-vibratile condition of the walls from the presence of solid matter within the chest; but solids do not necessarily cause an absence of tone. Thus, it is true that, if I strike over the liver or a chest full of fluid, I have what is called a dull sound, but if I strike over the sternum or head a different note is elicited. In this case, it shows that the bone itself produces a sound; but, apart from this, the solids and fluids produce different notes, as would be seen by striking a barrel full of fluid, and a solid block of wood of the same size and shape. Such a mass vibrates, but the vibrations are shorter than in the hollow barrel, and not so enduring, and a high-pitched note is produced. This, then, is the term for a note which we often meet with in striking over a solid organ or a hepatised lung. I will take this opportunity of saying, also, that vibration and non-vibration of the chest do not necessarily indicate the presence of air or liquid beneath, for, in the case of the barrel, if a thick piece of paper were spread over its inner surface, it would not vibrate on slight percussion, and it might then be thought that the vessel was full. An analogous condition occurs in the human chest, when a thick layer of pleura lines its inner surface. This prevents vibration when the chest is percussed, and the impression conveyed to you might be that of fluid in the chest, and thus it has happened that persons have been tapped for fluid, when they have had nothing more than a thickened pleura. There is also the converse fact, that a vessel may be so full of air and tightly stretched, that it will not vibrate, and thus the hollow sound does not appear; this may occur in pneumothorax, and is sometimes met with in extreme tympanites of the belly, where, from the great stretching of the stomach and intestines, no tympanic sound is elicited. The experiment may be artificially made by blowing out a bladder, which is resonant or tympanic until stretched to the utmost, when the tympanic sound is lost.

I shall leave you with these four conditions of the chest, viz., where it is full of air, fluid, a solid, or spongy lung, as the most important, and let you learn up minor conditions afterwards. I will, however, speak of two other sounds, which it is necessary to remember. I told you that when you struck over

a hollow space you had a tympanic sound, but this term is applicable only to the drummy state produced by a very large collection of air. If the hollow be circumscribed, as in a cavity in the lung, we adopt the term amphoric, which is a sound resembling what is produced by flipping the cheeks when stretched to the utmost, or a hollow India-rubber ball. An important modification of this is the cracked-pot sound, produced under the same circumstances as before, but with the addition of a hole in the cavity communicating with the external air. Thus, it would be produced in the India-rubber ball with a hole in its walls, or it can be produced in the cheek by slightly separating the lips, or still better by striking the closed hands on the knee—the air rushing out between the fingers producing an almost metallic ring. In the case of a cavity, we request the patient to open his mouth, and then, if there be a bronchial tube leading from the cavity direct to the trachea, and we strike sharply over the cavity, a well-marked cracked-pot sound is produced. This is almost pathognomonic of the existence of a vomica, for it is seldom heard under any other circumstances; on one or two occasions, in cases of hepatisation of the upper lobe, I have heard a sound somewhat resembling it. In children also with elastic chests, it is easy to produce it by striking the walls whilst they are crying.

Under the head of percussion, I might refer to another physical condition, which becomes apparent during the act of striking. I mean the sense of resistance. When you percuss over a resonant or dull chest your finger appreciates the vibration, or the want of it, and not only this, but it is aware whether a spongy or hard substance is beneath. In the latter case there is not the slightest giving way of the ribs, and the finger appreciates, by a sense of resistance, that there is a solid beneath.

(To be continued.)

FORENSIC OPHTHALMOLOGY.

ON INJURIES OF THE EYE IN THEIR MEDICO-LEGAL RELATIONS. BY PROFESSOR ARLT, OF VIENNA.*

As a member of the Committee of Experts of the Faculty of Medicine in the University of Vienna, I have often observed that medical practitioners go to work very superficially with regard to injuries of the eye, as regards both their recognition of the fact and their judgment as to its consequences. Even in conscientiously prepared reports, it may be perceived that the authors have not been well grounded in this department. The principal cause of this appears to me to be, that most have not the opportunity of obtaining instruction in this difficult subject, which is generally passed over in clinical treatises and in text-books. The monographs on the subject—I am acquainted only with those of W. Cooper, and of Lander and Geissler—are almost exclusively adapted for specialists, and are either unknown or accessible with difficulty to most medical men in practice. I have, therefore, concluded to sketch a brief description of the injuries of the eye, with special reference to the wants of those who are required to give medical evidence in courts of law.

* *Wiener Medizinische Wochenschrift*, March 7 and 14.

[Professor Arlt assumes that his readers are acquainted with the use of the ophthalmoscope, and with ordinary modern means of investigating vision and its defects.]

I divide the injuries of the eye into three principal groups.

1. Injuries from sudden compression or concussion of the eyeball.

2. Injuries from the penetration of a mechanically acting body into the tissues, a foreign body being left on, in, near, or behind the eyeball. Injuries of the lids, of the lacrymal organs, of the bony structures, &c., are for the sake of brevity conveniently left to the province of surgery.

3. Scalds of the eyeball and lids, and injuries of these parts by corrosive agents, so far as they demand special consideration in consequence of the manner in which they are produced.

Finally, in a fourth division, some remarks will be made on the recognition of artificially produced, exaggerated, or feigned lesions of the eye.

In each of the above named groups, an anatomical arrangement (according to the individual structures) will be adopted as most convenient, and the subjects will be considered in relation to diagnosis, prognosis, and treatment. In this way only, it seems to me, is it possible to obtain the necessary instruction regarding complicated injuries. An exposition of the principles of treatment I regard as necessary, because the question often arises, whether the unfavourable result of an injury is to be attributed entirely or in part to neglect or to improper treatment.

In every case, the visual power, not only of the injured eye but also of the sound one, should be separately examined. The injured eye may be the one on which the patient has hitherto depended for his means of earning his livelihood. Later on, if the second eye become sympathetically affected, it may be necessary to have determined its power of performing its functions at or soon after the receipt of the injury. The distinction between light and shade (quantitative sensibility to light) may be lost for a time (through abundant sanguineous effusion in the vitreous humour), or permanently. As regards the amount of qualitative vision, the degree of central acuteness of sight must be determined numerically; e.g., by ascertaining at what distance the fingers when held up in mid-day light cannot be counted, and at what distance letters and objects of a certain size—such as Snellen's and Jäger's test-type—can be recognised. It must then be ascertained whether the recognition of such objects at certain distances can be brought about or improved by the use of spherical or cylindrical concave or convex glasses; and whether the necessity for such means of correcting vision is to be treated as a consequence of the injury. No less important is the examination of indirect vision—its impairment, its partial or total loss. When no finer distinctions are required, it will be sufficient to close the patient's sound eye, and to make him direct the injured one steadily towards an object (such as a finger) held at the distance of about ten feet, and to gradually carry the finger (or a lighted candle in a dark room) from the periphery of the field of vision towards its centre, and to make the patient name the number of objects held up. It is only when neither central nor peripheral vision appears obscured, and where obscurity does not set in in the further progress of the case, that an ophthalmoscopic examination may be considered unnecessary.

In ascertaining the relation between the result of the examination and the *causa nocens*, it must always be borne in mind that important abnormal conditions not unfrequently affect the eye, the existence of which, although they have already existed, has not been detected; this is necessary, in order to avoid ascribing to the injury that for which it is not at all or only partially responsible.

I. SUDDEN COMPRESSION OR CONCUSSION OF THE EYEBALL.

1. *General Remarks.*—In this category we range first those injuries which are produced by the violent action of a blunt instrument on the eye, and by which the structures of the organ are pressed together, the agent itself not being left in the tissues. The globe is then either partially bruised or injured, or is flattened for the time by a more extensive pressure. Herewith are associated the cases in which the eye is thrown into sudden and strong vibration by violence affecting it, as well as the head and the entire body.

An eye which has suffered an injury of this kind shows, immediately or after a short time, the following appearances, independently of those presented by the lids: ecchymosis of the connective tissue, cloudiness, with subsequent inflammation (suppuration) of the cornea, sometimes with, sometimes without, slight wound of the surface; bursting of the sclerotic not far from the cornea (very rarely in the posterior part); effusion of blood in the chambers of the eye; more or less evident laceration of the iris; paralysis of the sphincter (rarely spastic contraction); paralysis of accommodation; bursting of the capsule of the lens; stretching or laceration of the zonule of Zinn, with more or less change in the position and form of the crystalline lens; laceration of the choroid, with effusion of blood into the vitreous chamber, and disturbance of the functions of the retina. According to Dr. Berlin's researches, escape of blood into the neighbourhood of the corpus ciliare occurs as a result of sudden compression of the eyeball, but cannot be directly ascertained except after death. Any one of the above-named results of injury may be present singly; but generally several of them are found to co-exist.

The detection of many of the above-mentioned changes may for a time be hindered or rendered very difficult by effusion of blood in the chambers or in the vitreous humour, and afterwards by the products of inflammation or by consecutive opacity of the lens. Hence, in many cases, a decisive opinion as to the situation, extent, and consequences of the changes produced, cannot be pronounced until after observation has been continued for weeks or months.

Our attention is very often directed to injuries of this kind not only by the history, but by the signs of contusion of the lids, of the edge of the orbits, and of the head. One may, however, on finding wounds or scalds, be led away from searching for contusion or concussion of the eye.

In order to understand the immediate effects of sudden compression, it must be borne in mind that the non-compressible fluid contents of the globe—the aqueous and vitreous humours—are enclosed in membranes, which have only a limited power of elastic expansion, and that the capsule of the eyeball is surrounded for more than half of its extent by the fatty tissue of the orbit, and that, under strong pressure, the capsule may very possibly become pressed against the orbit. Partial compression of the globe at

the point diametrically opposite that to which the force is applied cannot occur, on account of the thick and elastic packing of the globe; and therefore it is unnecessary, for the explanation of the changes in the posterior part of the eye, to assume, as Dr. Berlin and others appear inclined to do, that circumscribed compression of the tissue at that part has taken place.

When a foreign body acts on the coat of the eye with a certain amount of sudden violence, and, in consequence of its physical properties (size or bluntness) does not penetrate the part, its action may be confined to contusion, or, according to its size and shape, it may lead to local cracking or flattening, while at the same moment there is no remarkable pressure of the whole globe towards the cushion of fat or (when the force acts from behind) towards the lids. On account, however, of the incompressibility of the fluid contents, cracking or flattening cannot take place without a simultaneous change in form of the whole globe. The eyeball must, if the point where the force is applied be taken as a pole, and the direction of the blow as the axis of a sphere, be widened in the direction of the equator of that sphere. Resistance in the opposite wall, spread over a large surface, can only increase this change of shape. The presence of a breach or of a circumscribed hard body in the wall towards which the globe is forced, would indeed be liable, if there were a breach, to produce protrusion or rupture, and if there were a hard body, a fissure or perforation of the sclerotic. Such conditions, however, are scarcely present in any case. Just as little is it possible for the blow to be transmitted within the eyeball to a point diametrically opposite, if we suppose that the blow is applied perpendicularly to the plane of the point attacked. When the force is not applied perpendicularly to the plane, a part of the compressing force is lost. The vitreous and aqueous humours distribute the force in all directions to the surrounding walls. Consequently, the signs of compression or laceration of the retina are not to be looked for at the point diametrically opposite that where the force has been applied. To endeavour to explain, as Knapp has done, the changes produced in the choroid opposite the part struck in the same way as the fissures of bone and intracranial hæmorrhage in fracture of the skull—by *contrecoup*, is inadmissible; since the sclerotic possesses neither the hardness nor the absolute inextensibility of the cranial bones, and especially because no rupture of the sclerotic may be present at the point where there is hæmorrhage or rupture of the choroid; indeed, rupture of the sclerotic rarely occurs at this point.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

ONIMUS ON THE INFLUENCE OF ALBUMINOID SUBSTANCES ON ELECTRO-CAPILLARY PHENOMENA. It was discovered by M. Becquerel that, when two heterogeneous liquids are separated by an organic membrane, or by a capillary space, an electric current flows, which is capable of producing chemical and mechanical effects. In this way, metals have been reduced and double decompositions obtained, which do not take place in ordinary circumstances. M. Onimus has observed (*Comptes Rendus*, March 2),

that the interposition of a layer of albuminoid substance (white of egg, or albumen of blood) between the two liquids, may cause the same electro-chemical phenomena. His method is as follows. Into a U-shaped tube he first puts albumen, so as to fill the bottom part; then he gently pours into the limbs the liquids that are to react on each other. Ere long the solutions meet in the albuminous layer, and produce the phenomena in question. Thus, with sulphate of copper solution on the one side, and oxalate of potash solution on the other, there are formed beautiful blue crystals of binoxalate of copper and potash. Similarly, with sulphate of soda and nitrate of lime, crystals of sulphate of soda and lime are obtained. These crystals, in this case, always form a granulated mass, and not stalactites (as when membranes are used). The author considers that the importance of electro-molecular actions in physiological chemistry is further demonstrated by this action of albuminoid substances. In the osseous substance, *eg.*, we may readily understand the formation of phosphate of lime. By separating, with a layer of albumen, phosphate of soda and nitrate of lime, or chloride of calcium, we obtain phosphate of lime on the side on which the phosphate of soda has been put. He draws the practical inference that it is perhaps more advantageous to administer these salts separately than phosphate of lime directly, as the production of this salt takes place readily in the system.

Further, while neither chloride of calcium nor phosphate of soda causes coagulation of albumen, there is a very manifest coagulation, or (as if) a series of membranes, in the region where the double decompositions occur. It may be affirmed, in general, that there is always coagulation, more or less pronounced, wherever electro-molecular currents are produced, even where liquids are employed which do not directly cause coagulation. This coagulation is probably due to these very currents, for it only occurs on the side which may be considered as the positive pole. Another fact is stated by M. Onimus as important in its bearing on the phenomena which occur in the animal organism. M. Cl. Bernard has shown that all the salts of iron, passing through the system, undergo a chemical transformation, consisting of a deoxidation or passage to the state of protosalt. Now, this very transformation occurs when perchloride of iron is in contact with albumen in the apparatus, red prussiate of potash being on the opposite side. A well-marked blue border was observed in two or three days, which went on increasing, and which indicated the change of perchloride into proto-chloride of iron.

A. B. MACDOWALL.

DELORE ON MATERNAL CIRCULATION IN THE PLACENTA.—At a recent meeting of the Biological Society of Paris (*Le Mouvement Médical*, February 21), M. Delore read a paper detailing his researches in confirmation of the fact, affirmed by Weber, Kölliker, Turner, and Wenckler, that the blood of the mother circulates in the placenta.

The placenta presents to the naked eye—1. A circular sinus, or, in default of this, orifices like lattice-work; 2. Vascular orifices situated on the surface, or at the periphery; 3. Peripheric or central lacunar sinuses. Under the microscope, it shows an epithelium in the circular sinus.

M. Delore concludes that the placenta is situated on the passage of the uterine sinuses, and that it is,

therefore, nothing but a venous sinus penetrated by villousities. He is supported in his views by the following observations and proofs.

1. An injection made by the circular sinus penetrates the whole of the placenta, and the same thing takes place if an injection be made by the umbilical vessels.

2. The placenta of the still-born infant, of which the blood has lost the colouring matter, shows recent clots in its interior.

3. All the collected sections of the placenta show villousities in contact with blood-corpuses.

4. The presence of the vascular epithelium in the placental sinuses is a further proof that blood passes through them.

SURGERY.

STEUDENER ON CASES OF WOUND OF THE HEART.—Amongst severe injuries of the thorax occasioned in war-time, by stabbing or gunshot wounds, those of the heart are relatively rare; they are more frequently observed after duels, murders, or suicides. Non-penetrating wounds of the heart are especially rare, so much so as scarcely to receive mention in the recent surgical handbooks; on this account, the history of the following case by Dr. Steudener, of Halle (*Berliner Klinische Wochenschrift*, February 16) possesses some surgical interest.

E.K., twenty-three years old, had previously always enjoyed good health. On March 13, 1872, he shot himself under the left nipple with a revolver; he was found immediately afterwards lying on the ground, perfectly conscious, but unable to move the lower extremities. A wound with contused, scorched, and blackened edges, which did not bleed, was observed just below the nipple. There was complete motor and sensory paralysis of both lower extremities. The patient was perfectly conscious, and did not suffer much pain. Shortly afterwards a small quantity of clear blood was coughed out of the wound. On examining the chest, the left side was nowhere dull, but appeared somewhat tympanitic. The area of cardiac dulness was normal in extent and in position; a slight friction-sound could be heard over the heart; the vesicular breathing was very weak on the left side; on the right there was nothing abnormal. The wound was simply bound up, and ice applied. The following day there were marked pericarditic friction-sound and strongly marked symptoms of pneumothorax; tympanitic resonance over the whole of the left side of the chest, displacement of the heart to the right of the middle line, great dyspnoea, and a very weak small pulse. In the neighbourhood of the wound, the skin was raised by bullæ. The paralysis of the lower extremities was still complete. From the umbilicus downward there was no trace of sensibility; the bladder and rectum were paralysed; the urine was drawn off with the catheter. During the next three days the severity of the pulmonary and cardiac symptoms somewhat increased, and then they gradually diminished, and after three weeks had completely disappeared. A physical examination gave no evidence of either pericardial or pleural exudation having taken place, at least to any considerable extent. The wound in the thorax closed, but no change occurred in the paralysis; incontinence of urine after a time set in, and a bed-sore

formed over the sacrum. It is worthy of remark that, whilst the portions of the body not paralysed became emaciated, no such change took place in the paralysed parts. The bed-sore gradually increased in size, and the patient died, completely exhausted, fifteen weeks after the injury. At the *post mortem* examination, the muscles of the upper half of the body were found thin and pale, those of the lower were the subject of fatty degeneration. On opening the thorax both lungs collapsed equally, there was no trace of effusion in the pleural cavities, and, with the exception of a slight pleural adhesion of the left lung, nothing whatever abnormal was found in either. The heart was somewhat hypertrophied, and adherent throughout to the pericardium. On the outer surface of the left ventricle, near the apex, was an oblique cicatrix, which could be made to protrude considerably on injecting the heart with water; this corresponded to a hole in the pericardium, in the edges of which, as well as in the substance of the heart itself, were imbedded numerous spicules of powder. The muscular tissue of the heart, and its valves, were otherwise completely normal. Between the attachments of the tenth and eleventh ribs to the spine, some particles of powder were observed in the parietal pleura. In the abdomen, there was much fatty tissue in the omentum. The liver was enlarged and fatty; as were also the kidneys. The renal pelves and ureters were dilated, and the bladder was strongly contracted. The thoracic and lumbar part of the spine was removed and carefully opened. The ball had entered the intervertebral foramen between the tenth and eleventh thoracic vertebrae, and after completely dividing the spinal marrow, had then lodged in the body of the vertebra, projecting partly into the spinal canal. Some new bone had been formed in its neighbourhood. The divided portions of the cord were connected by a thin streak of cicatricial tissue; the lower portion was softer than the upper, and the grey matter was difficult to distinguish in it. The ball had thus probably passed through the anterior edge of the left lung, traversing the pericardium, and grazing the apex of the heart during the period of systole; it afterwards penetrated and lodged in the spinal canal.

The quick and favourable healing of a penetrating chest-wound without a trace of suppuration in either the pericardial or the pleural cavities, and in spite of well marked pneumothorax, is remarkable. It is also remarkable how little interference was produced in the heart's action by the occurrence of the injury; it is not unlikely that, had the patient survived, the thinning of the ventricular wall might have led to the creation of an aneurism of the heart; a slight degree of protrusion could indeed be observed at the necropsy. The visible emaciation of the non-paralysed portions of the body as compared to the paralysed, where there even seemed to be increased fat formation, was very unusual. 'I had,' the author states, 'previously examined many cases of fracture of the spine with complete paraplegia, and in this particular found all parts of the body equally affected.'

WILLIAM MAC CORMAC.

HICQUET ON WOUND OF THE HEART.—Dr. Hicquet, in the *Presse Médicale Belge*, no. 11, 1874, relates a remarkable case of perforation of the heart by a ball without injury to the pericardium.

A young man aged twenty-four was found dead with a gunshot wound in the front of the chest. At the *post mortem* examination a contused circular wound,

with blackened inverted edges, was observed in the fourth intercostal space close to the right of the sternum. Between the chest-wall and the surface of the pericardium, a cylindrical ball was found, surrounded by infiltrated cellular tissue. The pericardium was distended with blood, partly fluid, partly coagulated. Penetrating the right ventricle was found a circular wound with depressed slightly contused edges, somewhat less in diameter than the ball. The heart was strongly contracted and its tissue healthy. The lungs were congested.

Of the condition of the parts there appeared to be no doubt. The pericardium was uninjured, while the ball caused a wound of the ventricle.

W. MAC CORMAC.

NUSSBAUM ON A NEW METHOD OF CURING ULCERS.—Dr. Nussbaum, of Munich (*Ärztliches Intelligenzblatt*, no. 14), believes he has discovered a successful mode of dealing with large indolent ulcers. He has treated sixty cases of extensive ulcer of the leg in the following manner with the best results. The patient, having been first anæsthetised, an incision is made completely around the sore from half to three-quarters of an inch from its margin, dividing the skin and superficial structures down to the muscular aponeurosis. Very free hæmorrhage results from the wound, and it is necessary to fill the incision throughout its length with lint or charpie, and to apply firm compression; the charpie also acts in preventing immediate union of the incision. On the second day, the interposed lint is removed, and water-dressing is employed until cicatrization is completed. The author states that a surprising change is observed in the ulcer after the first twenty-four hours. The secretion alters from thin foul-smelling pus, very abundant in quantity, into normal inodorous pus, and the quantity becomes but small; the former ulcer diminishes rapidly in size, and cicatrization, proceeding from the margin towards the centre, soon becomes complete. The diminution in the amount of the secretion, and the other favourable changes that take place, are explained by the fact that the incision divides a large number of engorged vessels, and that the nutritive elements, which were before carried away in the copious secretion, have now time for cell-proliferation and transformation into connective tissue. The author believes that by means of this treatment a more rapid cure is obtained, and that the cicatrix is more elastic and resistant, than after the use of ordinary methods. The plan advocated by the author resembles the method often employed with advantage in indolent ulcers with raised callous edges, of making a number of radiating incisions through them.

WILLIAM MAC CORMAC.

HUTCHINSON ON REMOVAL OF THE UPPER JAW WITHOUT EXTERNAL INCISION.—Dr. Hutchinson reports (*American Journal of Medical Science*, January, 1874) what, so far as he has been able to ascertain, he believes to be the only case which the annals of surgery furnish, in which the entire right upper jaw and malar bones have been removed without external incision. The necrosed bones, their death being due to the fumes of phosphorus, were detached in the following manner.

The cheek was well retracted by a cheek-holder, and an incision was made from the right central incisor along the centre of the alveolar ridge to its posterior margin. The periosteum was separated by a perios-

teome from the anterior surface of the upper jaw, around to its junction with the pterygoid process of the sphenoid bone and upward to the malar bone, which also was found to be dead. This was likewise denuded of periosteum, as was also the floor of the orbit. An incision was then made down to the bone along the transverse palate suture outward to the alveolar process, and another forward along the middle palate suture. The periosteum was now separated from the palatine process of the superior maxilla. The speno-maxillary fissure was perforated, and the broadest part of the malar bone divided directly opposite to the perforation, by a single cut with Isaac's right-angled forceps. The nasal process of the superior maxilla was divided by the same instrument, in an oblique direction from the lower termination of the os nasi to the edge of the orbit, leaving the os unguis and the superior extremity of the nasal process of the superior maxilla undisturbed, in order to preserve the lachrymal sac from injury. One blade of the right-angled forceps was then introduced into the right nostril, and the other into the mouth, and the palatine processes of the superior maxilla were separated as far back as the palate bone by a single cut; and the disunion of the bones concerned was finally accomplished by separating the upper maxillary from the pterygoid process of the sphenoid bone. The jaw was now grasped with a duck-bill forceps, and with a slight twist the whole of the bone (except the upper end of the nasal process), including the orbital plate, was readily removed. The malar bone was seized with the forceps and removed in fragments. The periosteum covering the bones was left intact. The palate bones were uninjured, so that the whole of the soft palate was preserved, supported by the palatine plate of the os palati. The hemorrhage attending the operation was considerable, but was easily arrested by stuffing the wound with charpie wet with a solution of carbolic acid (1 part to 120 of water). The patient, a girl aged eighteen, recovered without an unfavourable symptom.

G. W. CALLENDER.

HUTCHINSON ON OSTEOMYELITIS OF THE ULNA. Dr. Hutchinson also mentions (*ibid.*) a case of osteomyelitis of the ulna, terminating rapidly in complete death of the bone. The lower end of the shaft was found, when removed, to be diminished in size, a condition which, it is observed, could only be produced by the action of some acid upon the osseous tissue, probably the lactic acid, which is known to be generated by decomposing muscular tissue and pus. The entire ulna was in this instance excised.

G. W. CALLENDER.

BOURGUET ON PSEUDARTHROSIS OF THE FEMUR CURED BY IRRITANT INJECTIONS.—M. Bourguet d'Aix communicates to the Société de Chirurgie (*L'Union Médicale*, Feb. 10) under this title the account of a case similar to one which he reported in 1863. A man broke the neck of his thigh-bone on Oct. 28, 1872; on April 1, 1873, it was still unconnected. M. Bourguet then injected at the level of the superior fragment ten minims of a solution of ammonia (one part in three). On April 27 he injected twenty minims at the level of the superior fragment; on April 30 he injected twenty drops between the two fragments; on May 8 he injected twenty drops of a solution of equal parts of ammonia and water. The limb was fixed on a splint. On May 10, he injected twenty drops of an iodised solution; and repeated it on June 2,

4, and 14, when a silicated bandage was applied to the leg, thigh, and pelvis. Phosphate of iron was given internally. On September 1 the patient was able to walk; on September 17 the fragments were solidly united, the callus was voluminous, there was shortening to the extent of $2\frac{1}{2}$ centimètres; another bandage was applied, leaving the knee and ankle free. On November 27, the cure was complete.

DESPRÈS ON AMPUTATION IN THE CONTINUITY OF THE FIRST AND FIFTH METATARSAL BONES.—Dr. Desprès, Surgeon to the Hôpital Cochin, points out (*Bulletin de Thérapeutique*, Jan. 30, 1874) that, for lesions of the metatarso-phalangeal joints, disarticulation of the phalanx is not sufficient, and that most surgeons are of opinion that the head of the metatarsal bone should be removed at the same time; when the whole metatarsal bone is removed, the tarso-metatarsal joints are opened, which is a disadvantage. The many operative proceedings recommended have for their object to remove the cicatrix from the influence of subsequent pressure, or at least to avoid a plantar cicatrix. Notwithstanding the precautions taken, the cicatrix is found sometimes on the side of the foot where it is exposed to pressure, or adherent to the end of the bone, where it is sure to be painful. The author adopts a method which he has seen Richard employ, and calls it a racquet-shaped incision with external flap. He adopted it in four cases recently with good results. An incision is made commencing near the prominence corresponding to the posterior extremity of the metatarsal bone, easily recognised by a distinct elevation under the skin; the cut is made to pass obliquely upon the dorsum of the foot until it comes to the base of the toe by an almost semicircular incision, with the convexity turned to the middle line of the foot; the incision is then continued around the base of the toe and so as to return to the first incision. The flap thus formed is dissected from the bone; that done, the metatarsal bone is encircled by an incision with the bistoury, in order to separate the soft parts. Regard being had to the age of the patient and the resistance of the bone, either Liston's forceps or a handsaw is used; in the latter case, a retractor must be employed to protect the soft parts.

The operation is stated to be easy, and the end of the divided bone does not approach the cicatrix. An account of four cases is then given, the subject being in each case able to walk afterwards in an ordinary shoe without any difficulty. W. MAC CORMAC.

MINER ON AMPUTATION AT THE SHOULDER-JOINT.—Dr. J. F. Miner, in the *Buffalo Medical and Surgical Journal*, says:

'The rule in surgery, which seems to be fully established, that the nearer the body the greater the risk in amputations, suggests the propriety in hip and shoulder-joint operations of considering carefully any measures of procedure calculated to diminish this risk. Professor McGraw, of Detroit, suggested the capital idea in hip-joint amputations of removing the bone from the acetabulum, when practicable, and dividing the soft parts at a greater distance from the body, thus avoiding the division of so great amount of tissue, and really removing the amputation to the junction of the upper and middle third, or even lower than this in some cases. I had practised upon this idea in injuries of the shoulder-joint, but had not considered the importance of the principles involved until reading his paper, when the value of the suggestion was better appreciated.

'In injuries of the bone and soft parts about the shoulder, it is not very unusual to be able to remove the shattered bone from the joint, and divide lower down upon the arm the lacerated soft parts of the arm, which in the usual method of amputation at the shoulder-joint were wholly sacrificed. These boneless stumps are of no great value in the motions or adjustments of artificial arms, but they are not altogether useless; they maintain the contour of the shoulder, and, above all, it is believed that oftentimes the risks attending the operative procedure are greatly lessened, and the operation, in controlling hæmorrhage and tying the vessels, much simplified. The results of some recent cases have impressed me with the conviction that, when the system is greatly reduced by loss of blood or from effects of long-continued disease, the value of this procedure cannot be over-estimated.

'A patient entered the General Hospital, at my request, for the purpose of exsection of a part or the whole of the humerus, as found necessary. Being bloodless and suffering from profuse purulent discharge, it was hoped that increase of strength and flesh might be obtained by a few weeks delay of the operation. Disappointed in this, it was soon apparent that he must lose his arm or life, or probably both, the disorganisation of the arm being complete, having become a suppurating mass from within five or six inches of the joint throughout. The idea of making the usual operation of amputation at the shoulder-joint was scarcely feasible, as our patient was hardly alive, and could not be expected to bear much operative interference. The diseased bone was divided near the middle with a chain-saw, and the upper fragment carefully detached from the soft parts and glenoid cavity and removed. The vessels were now easily controllable by grasping through the soft parts, and at a distance of about five inches from the joint the soft parts were divided, the vessels tied and parts approximated and retained by adhesive plaster, and warm-water dressings applied. To the surprise of us all, the patient did not seem to suffer from the operation, no blood was lost, and but little living tissue was divided. He made a good recovery, gained rapidly in flesh and strength, and left the hospital in three months fully recovered.

'The second case of this character was from railroad injury. The attempt to save the arm having failed, Dr. Green, of Buffalo, invited me to amputate at the shoulder-joint. Mortification had left a line of demarcation four or five inches from the joint. The bone was shattered, and now partially separated from the soft parts. With but little hope of saving the life of this patient, we yet removed the bone to the joint, divided what of tissue remained alive at about five inches distant from the body, laid the parts gently together, retaining them with plaster, and applying warm-water dressings. This patient recovered without an unpleasant symptom after the operation, from a condition of depression and bloodlessness, which, according to my observation, is generally fatal.

'My third case is a recent one, and more strongly impressed me with the advantages of removing the bone first, and then dividing the soft parts at as great distance from the body as circumstances will permit. A young man had an arm lacerated and completely destroyed by railroad accident. The soft parts were torn to within about four inches of the body, the bone broken to near the joint, the fragments loose and pointing into the flesh in all directions. The

patient, suffering from shock and loss of blood, was so nearly pulseless that it seemed scarcely proper to make any interference; but after delaying for the effects of stimulants a little, the head of the bone was carefully disarticulated from the glenoid cavity and the brachial artery ligated. After this, the remaining soft parts were divided at a distance of about four inches from the body, and the parts loosely approximated with a suture or two and adhesive strips. The patient rallied, and gradually recovered. This process consists in simplifying the operation as much as possible, and in this I believe consists the advantage of the procedure.'

APPLIED PHARMACY.

VACHELL, SMITH AND OTHERS ON SOLUTIONS OF MORPHIA FOR HYPODERMIC INJECTION.—MR. C. T. Vachell suggests (*Lancet*, Nov. 29, p. 797) the desirability of fixing a standard strength for the solutions of morphia used for subcutaneous injection. To obtain a clear solution, without excess of acid, is not very speedily effected; and he thinks it would be a convenience to the practitioner to be able to purchase a carefully prepared solution of standard strength. Mr. Vachell proposes the following formula.

| | | |
|---------------------|---------|---------------------------|
| Acetate of morphia. | | 1 drachm. |
| Distilled water | | 12 drachms. |
| Acetic acid | | As much as is sufficient. |

He states that one-twelfth of a grain of acetate of morphia would be contained in a minim of such a solution; the dose would, therefore, be from two to four minims. Some such formula, he thinks, might be inserted in the next edition of the *British Pharmacopæia*.

Dr. White has since pointed out (*Lancet*, Dec. 20) that no allowance is made in the foregoing for the increase of bulk by the addition of the solid, and that a minim would contain not one-twelfth, but one-thirteenth. He says that he makes his solution as follows:—

| | | |
|--------------------|---------|------------|
| Acetate of morphia | | 1 scruple |
| Distilled water | | 140 minims |
| Acetic acid; B. P. | | 5 minims |

Dissolve with gentle heat in a test tube. The solution measures exactly 160 minims, consequently 8 minims would contain one grain of acetate of morphia. As a standard solution he suggests one-half the strength of the above. The hydrochlorate is used by Mr. White (*Lancet*, Jan. 3) in the proportion of two grains to one drachm of hot water. This he has found to form a solution that does not deposit on cooling, and which he thinks preferable to solutions made up with free acids. In the discussion that has taken place the *British Pharmacopæia* solution of the acetate has also been recommended and objected to because of its bulkiness, and suggestions have been made for the use of a standard syringe as well as a standard solution.

Messrs. T. and H. Smith (*Pharm. Journ.* vol. iv. p. 436) state that, by using meconic acid instead of acetic acid, a neutral and stable solution of one in twelve, or much stronger, may be prepared. They consider that a neutral solution of meconate of morphia is pre-eminently adapted for hypodermic treatment.

GERRARD AND ABRAHAM ON PHOSPHORETTED RESIN.—MR. A. W. Gerrard stated at a meeting of the Pharmaceutical Society (*Pharm. Journ.* vol. iv. p. 441) that he had found resin would dissolve readily at least 4 per cent. of phosphorus, and he described the preparation of a phosphoretted resin for use in pharmacy. A strong wide-mouthed, well-stoppered bottle is weighed and filled with melted resin, again weighed, and four parts of phosphorus added for every 96 parts of resin. The phosphorus should, if possible, be added in one piece, and care should be taken that the resin is in a fluid state, so that the phosphorus may readily sink below the surface, or else it will take fire. The stopper being tightly fixed, the bottle is placed in a previously warmed sand-bath, and digested at 200° C. (392° Fahr.), with frequent shaking until the phosphorus is dissolved. If the temperature exceed 210° C. (410° Fahr.), the resin boils, and the heat is liable to change the phosphorus to the red amorphous state. To prevent accidents or the volatilisation of the phosphorus in the upper portion of the bottle, a bottleful of the resin should be made at each operation. The resin is most easily removed by drawing it from the bottle while still soft and only partly cooled, under hot water.

The formula suggested by Mr. Gerrard for the administration of this phosphoretted resin is as follows.

| | |
|---|------------|
| Take of Phosphoretted resin (4 per cent.) | 25 grains. |
| Powdered white sugar | 75 grains. |
| Tincture of tolu | q. s. |

Pulverise the resin, mix with the sugar, and form into a mass with tincture of tolu (eight or ten drops are sufficient). Divide into twenty pills. Each pill will contain one-twentieth of a grain of phosphorus.

The pill-mass formed is of excellent consistence, and the pills made from it retain their form and present an elegant appearance without the addition of any coating; they have but a faint odour of phosphorus, which may be completely removed by the addition of oil of peppermint, and they are readily soluble. Mr. Gerrard adds that experience gained in the University College Hospital shows that these pills are fully equal in therapeutic value to any form previously used.

The kind of resin to be used in this preparation is the black translucent variety known as rosin, not the pale yellowish variety usually met with in druggists' shops, unless it has been deprived of a varying amount of water (sometimes 10 per cent.) which it contains.

In commenting upon the above preparation (*Pharm. Journ.* [3] iv. 549) Mr. A. C. Abraham, of Liverpool, alludes to the inconvenience and danger attending the application of strong heat to phosphorus. He therefore proposes to substitute for the resin a substance that is fusible below the boiling-point of water, and also sufficiently heavy to sink in that liquid. Balsam of tolu he has found to answer both these requirements, and experiment has shown that 4 grains of phosphorus are perfectly dissolved by 96 grains of washed tolu, if melted together under water and well stirred. The preparation so made, he reports, when examined microscopically, does not show any particles of undissolved phosphorus, and when rubbed between the fingers in the dark is seen to give off a perfectly equally distributed light.

LUND ON CARBOLISED RESIN-CLOTH.—As an antiseptic dressing, Mr. Lund recommends the use of a carbolised resin-cloth in the place of the ordinary

cerecloth, the effect of the addition of resin being to neutralise the acrid properties of the carbolic acid, which still evolves an antiseptic vapour at the temperature of the body. He uses a very thin calico gauze, and the solution for its saturation is prepared as follows (*British Medical Journal*, Dec. 6, p. 654).

| | |
|---------------------------------------|------------------|
| Carbolic acid crystals (melted) . . . | 2 fluid ounces. |
| Castor oil | 2 fluid ounces. |
| Purified resin | 16 ounces. |
| Methylated spirit | 40 fluid ounces. |

To the resin liquefied by heat and removed from the fire is added one-third of the spirit; when these are well-mixed, another third of the spirit in which the oil has been previously dissolved is poured in; and lastly the acid dissolved in the remainder of the spirit is slowly added. The whole must be agitated until all the ingredients are thoroughly incorporated and afterwards passed through a muslin filter to get rid of extraneous matters. If this plan be not adopted, the resin will concrete into a mass at the bottom of the vessel, and it will be extremely difficult afterwards to get it perfectly mixed. Thus prepared, the solution is of a dark colour, clear, and free from any deposit, and can be kept unchanged for a long time in a well-corked bottle. The castor-oil is added that the cloth may retain its flexibility after the evaporation of the spirit.

To prepare the resin cloth a very cheap, thin, porous calico, or calico-muslin, is selected, known in the trade as 'mulls'; it should be unbleached, and free from dressing. This is divided into strips of about nine inches wide, and six yards long. The strips are carefully folded so as to lie flatly in a tin box, made so as to receive the plates of a tincture press, or an ordinary copying press, and having an aperture at the bottom of the box, with a tap so that the superfluous fluid can be removed and reused. The solution is poured over every layer of cloth successively, so as to wet every portion of it; next the pressure is applied, and the calico squeezed as dry as possible, then taken out and hung for a few hours in a well-ventilated, warm room, till all traces of smell of methylated spirit have departed. The cloth may afterwards be rolled up and kept in tin cases ready for use. It appears to be necessary to dry it thoroughly, as the presence of any traces of the methylated spirit is apt to cause irritation.

BOND ON EXTRACTUM AURANTII CORTICIS FLUIDUM.—A fluid extract of sweet orange-rind is extensively used in the United States, in the preparation of numerous elixirs and tonics. As no official formula exists for it, Mr. Monroe Bond has made numerous experiments to ascertain the most suitable menstruum, and recommends the adoption of the following formula (*Amer. Journ. Pharm.* vol. xlv. p. 482).

| | |
|--|--------------|
| Sweet orange-peel, in moderately fine powder | 3xvj. |
| Glycerine | fl. oz. iij. |
| Alcohol | |
| Water, each a sufficient quantity. | |

Mix fourteen fluid-ounces of alcohol with two fluid-ounces of glycerine; moisten the orange-peel thoroughly with twelve fluid-ounces of the above mixture cover carefully, and let it stand for twelve hours; then pack moderately firm in a percolator, and proceed as directed in the *United States Pharmacopœia* for the preparation of fluid extracts. Finish the percolation with a mixture of two parts of alcohol and one of water; reserving the first fourteen ounces, add

one fluid-ounce of glycerine to the remainder, carefully evaporate to two fluid-ounces, and mix with the reserved portion.

The preparation is described as having a heavy rich appearance, being permanent, and possessing all the aroma of the orange-peel. One fluid-ounce added to fifteen fluid-ounces of simple syrup, makes what the author considers to be a stronger and better syrupus aurantii corticis than the official, and which is free from any opaqueness. Four fluid-drachms of the fluid extract and a few drops of solution of citric acid mixed with a pint of syrup, make a delicately flavoured unfermentable syrup for use at the mineral-water counter.

VAN GORKOM ON JAVA CINCHONA BARKS.—Van Gorkom has continued his examination of Java cinchona barks. He reports (*Pharm. Zeitung*, Oct. 4), that the several varieties of Cinchona officinalis contain different amounts of alkaloids, varying in ten specimens examined, from 1.75 to 5.92 per cent. of quinine (= 2.35 to 7.98 of sulphate), and that the smallest leaved varieties are richest in quinine. C. Calisaya bark also varies much; one specimen of the 'Ledger' variety (see LONDON MEDICAL RECORD, ante p. 540), containing as much as 9.09 per cent. of quinine (= 12.23 per cent. of sulphate). The plant yielding this kind is always characterised by very small white flowers and small fruit. C. caloptera is stated to yield a bark well suited for pharmaceutical purposes, as also does C. lancifolia. The yield from C. Pahudiana bark was very unsatisfactory. The opinion that C. officinalis should be grown at a considerable elevation above the sea-level, is supported by the results. The progress of the plants this year is stated to have been satisfactory, and as much as 7,000 kilos of bark have been prepared for delivery.

ELLINOR ON A NEW PREPARATION OF KINO.—In a paper read at the meeting of the British Pharmaceutical Conference (*Pharmaceutical Journal*, [3] iv. 336), the author recommends the preparation of a concentrated solution of kino, miscible in all proportions with water, which could be diluted as required, and the inconvenience, frequently resulting from the instability of the B. P. tincture thus avoided. The formula he proposes is as follows.

| | |
|---------------------|------|
| Kino | 3j. |
| Glycerine | 3ij. |
| Water to | 3iv. |

Rub together in a mortar the kino, glycerine and 3j. of the water, until dissolved, then make up to fl. 3iv. by the addition of water.

The whole of the kino is dissolved, the sand and other earthy matter being thrown down after standing a week or so. The author states that one volume of this concentrated preparation mixed with four volumes of water will form a solution corresponding in strength with, or stronger than, the tincture.

[The many instances in which, during the last few years, glycerine has been introduced with advantage into pharmaceutical preparations, and the impulse to fresh experiments in that direction which will be doubtless given by its official introduction into the fluid extracts of the United States Pharmacopœia, should not cause the fact to be lost sight of that its use will probably often cause a considerable modification both in the ingredients and power of a preparation. This is especially the case when used with astringents. Thus Mr. H. B. Brady mentions

(*Pharmaceutical Journal*, iv. 336), an instance in which three hundred grains of perchloride of iron dissolved in glycerine were swallowed by mistake without any ill effect, whilst a very much smaller quantity dissolved in water must have caused serious results. He has also known several instances in which medical men have been disappointed in obtaining the full astringent effect they expected from glycerinum acidi tanici, when a strong aqueous infusion has answered admirably. The effect of glycerine in covering the astringent metallic taste of perchloride of iron was pointed out recently by Dr. Snow in the *British Medical Journal*, June 28, p. 724, and in the same publication the following week (p. 11), Dr. Boggs added further that glycerine counteracts the astringent action of some drugs upon the bowels, and suggested that when that effect was not needed it might be substituted for syrup as a vehicle in preparations of iron, cinchona, rhatany, etc., which have a tendency to constipate.—*Rep.*]

PILE, MAISCH, AND OTHERS ON ADULTERATED OIL OF GAULTHERIA.—At a recent meeting of the Philadelphia College of Pharmacy (*Amer. Journ. of Pharm.*, vol. xlv. p. 521) Dr. Pile called attention to a sample of adulterated oil of gaultheria. The adulterating substance he had found to be chloroform, in the proportion of one part to four parts of the oil. The adulteration could be easily detected by taking the specific gravity and the boiling-point; the specific gravity of pure oil of gaultheria is 1.18, that of the adulterated was 1.24; the boiling-point of the true oil is 400° F., the adulterated boiled actively at 200° F. Mr. C. Bullock described an apparatus for separating the substances by fractional distillation, by means of which he had found that there was a large proportion of oil of sassafras also present. Professor Maisch said that the presence of oil of sassafras might be detected by treating the suspected oil in the cold with commercial nitric acid, the oil of sassafras separating as a deep red resinous mass, whilst the oil of gaultheria was unaffected.

BAILLON ON THE BOTANICAL ORIGIN OF THE BALSAMS OF TOLU AND PERU.—The balsam of tolu is obtained from a plant which has been described as *Myroxylon toluiferum*, but was originally named by Linnæus, in his *Materia Medica*, *Toluifera balsamum*. This latter name, therefore, Professor Baillon thinks it should retain (*Répertoire de Pharmacie*, i. 566). The tree yielding balsam of peru was first named by the younger Linnæus *Myroxylon peruiferum*, afterwards by Klotzsch *M. Pereiræ*; but Professor Baillon considers it can hardly be separated specifically from *Toluifera balsamum* (*M. toluiferum*). The different qualities and characters of the balsams seem to depend entirely upon the method of their extraction. But all the forms of tolu balsamum have one constant character in the smooth surface of the seeds, which arises from the fact that the seeds are not ruminated; whilst in *M. peruiferum*, which should take the name of *Toluifera peruifera*, they are ruminated. In the latter, as in the former, the balsamic substance is present on the surface of the seed, but is sunk into the crevices of the seminal envelope instead of being deposited in a smooth layer. This Professor Baillon finds to be the sole difference between the two species.

B. H. PAUL, Ph.D.

OPHTHALMOLOGY AND OTOTOLOGY.

KNAPP ON NEW INSTRUMENTS RELATING TO THE EYE.—Dr. Knapp, of New York, describes some new instruments in the *Transactions of the American Ophthalmological Society*.

The first instrument is an improved lid-forceps. It has rendered him and his colleagues at the New York Ophthalmic and Aural Institute good service in various operations on the lids. The modification, which renders the instrument applicable to both eyes, seems to answer perfectly well.

The second instrument is a hook for the extraction of foreign bodies from the interior of the eye. It is a small hook, grooved and roughened at its concave side, made of flexible silver, so that its curve may be changed according to the requirements of the case. He has used this instrument for years with good results. Those who have had opportunities to remove foreign bodies from within the eyeball, will know how unavailable forceps are for this purpose: the foreign body, in most cases receding before the instrument, is pushed more deeply into the interior structures of the globe. The best instruments to extract foreign bodies out of the eye, and, in fact, the only available ones, are hooks and curettes. Dr. Knapp has extracted successfully a number of foreign bodies from the anterior chamber, some from the lens, and a few from the vitreous chamber.

The third instrument is a new ophthalmoscope. A rotating disc behind the mirror, first employed by Mr. Rekoss, of Königsberg, and modified usefully by Dr. E. G. Loring, of New York, seems to be the best mechanical contrivance for using the ophthalmoscope as an optometer. Loring's three discs, however, cause considerable loss of time by changing from one to the other; and Cohn's modification, which puts all the glasses of Loring's three discs into one large disc of 3 inches in diameter, appears clumsy and unmanageable. Apart from these inconveniences, the discs in Loring's ophthalmoscope have not a sufficient number of glasses for the requirements of a careful ophthalmic practitioner. Some years before Dr. Loring constructed his instrument, Dr. Knapp had a complete collection of small trial-glasses made, which he could insert into an ordinary small (Liebreich) ophthalmoscope; and Dr. H. D. Noyes had his ophthalmoscope so changed that he could place behind the mirror all the numbers of his trial case of spectacles. All this, however, requires too much time for constant use. Dr. Knapp's ophthalmoscope affords the greatest possible number of trial-glasses behind the eye, permits them to be rapidly changed, while the instrument is nearly as small as Loring's. It consists of the ordinary mirror, behind which two discs can be rotated like the diaphragm in some—for instance, Kellner's—microscopes. In each disc are thirteen little apertures, twelve of which are filled with glasses, one being empty. One disc contains convex, the other concave glasses, in the following progression: 3, 4, 6, 8, 10, 12, 14, 17, 20, 24, 33, 48.* The intervals of refractive power between these numbers are as follows: between 3 and 4 = $\frac{1}{12}$; 4 and 6 = $\frac{1}{12}$; 6 and 8 = $\frac{1}{24}$; 8 and 10 = $\frac{1}{40}$; 10 and 12 = $\frac{1}{60}$; 12 and 14 = $\frac{1}{84}$; 14 and 17 = $\frac{1}{78}$; 17 and 20 = $\frac{1}{112}$; 20 and 24 = $\frac{1}{120}$; 24 and 33 = $\frac{1}{38}$; 33 and 48 = $\frac{1}{106}$. The weaker

* In the new instruments + 2 and - 2 are added.

numbers, which occur more frequently in practice, show very small intervals of refraction. These two series of glasses are sufficient for the majority of cases coming before the practitioner. To avoid, however, any loss of time, both discs are placed behind the mirror, and the change from one glass to any other is effected by a very easy rotation of the disc. The discs are held in place and protected from being soiled by a thin metal plate, which covers the glasses from behind, whilst in front the discs are applied to the body of the instrument. The cover has three holes; the middle one corresponds to the perforation of the mirror; through the two others, placed respectively above and below the central one, the numbers of the glasses can be read. The cover can be removed if the glasses require cleansing. The vertical diameter of the ophthalmoscope, the handle, of course, not included, is 60 millimètres, not quite $2\frac{1}{2}$ inches; its horizontal diameter is 35 millimètres, not quite $1\frac{1}{2}$ inches.

The edges of the two discs overlap each other at the place of the perforation of the mirror, so that each glass of one disc can be superposed by each glass of the other disc, thus giving combinations of glasses which will satisfy all practical and scientific demands. It is easy to make intermediate numbers between the higher numbers of the discs. If it be desired to know the distance between two parts of the fundus oculi, for instance, the centre and the margin of the optic disc, the position of one part is determined by one disc, and so much refractive power is added or taken away by the other disc as is required to see the second part clearly. For instance, if the centre of an excavated papilla appear clear with -8 , the disc of the concave glasses is left with -8 behind the aperture in the mirror; the disc of the convex glasses is rotated, and it is found that convex 24 renders the margin of the papilla clear. Then the refractive difference between the margin and the centre of the disc is $\frac{24}{4}$, which indicates an excavation of 0.4 millimètres in depth.

GAYAT ON MEASUREMENT OF THE ORBIT.—The dimensions of the orbit as given by Arlt, Richet, Zander, and Wecker, differ from each other, owing to the various points from which they have been taken. In his paper (*Annales d'Oculistique*, July and August, 1873) Dr. Gayat records the results of his measurements made upon skulls at various ages, and of individuals of different nations. In shape, the orbit may be described as a quadrangular pyramid, though there is considerable disagreement as to the position of its apex. According to some authors, this is made to correspond with the optic foramen, and lines prolonged through the apex of each orbit would meet at the sella Turcica; according to others, it corresponds with the widest portion of the sphenoidal fissure, and a line prolonged through it would meet a similar line drawn through the fellow orbit at the internal occipital protuberance. Other points have been fixed upon, as the speno-maxillary fissure, and the narrowest part of the sphenoidal fissure, all of which must vary in size at different ages; and this being so, it will be readily seen how difficult it is to place reliance upon such measurements.

Again, with regard to the base of the pyramid, the points generally chosen are the angles of the orbital aperture and the margins of bone which enter into the formation of these angles, any of which may vary in their thickness and curvature.

According to Dr. Gayat, the most reliable point to

be chosen as the apex is the bony plate which forms the outer margin of the optic foramen; this is intermediate to the two points through which Cruvelhier and Sappey would make the axis to pass. By means of an instrument of his own, Dr. Gayat measures from this to various other points chosen from the margins of the orbit, such as the spine or tubercle which marks the groove for the tendon of the superior oblique; the suture which unites the external angular process of the frontal with the malar bone; the suture between the malar and the superior maxillary bones; lastly, the crest of the superior maxillary which forms the anterior lip of the lachrymal canal. Even these points are not constant in their position or size, so that it is evident how unsatisfactory ordinary measurements of the capacity of the orbit must be.

Though it varies in individuals of different races of men, the orbital aperture may be described as an ellipse inclined downwards and outwards. The Tasmanians have a very small orbital aperture, and its greatest diameter is horizontal.

Dr. Gayat calls his instrument an orbitometer, and has made measurements of a large number of skulls in the museums at Vienna and Paris; he finds that measurements of one orbit are sufficient, as the two cavities are usually exactly of a size. The paper contains valuable tables of measurements of a large number of normal skulls, as well as of others which were unsymmetrical and unusual, and concludes with the author's belief that the subject has a value and importance to anthropologists, and to surgeons other than those who are specially interested in the study of ophthalmology.

B. J. VERNON.

DOBROWOLSKI ON SMOKED GLASSES.—Dr. Dobrowolski, of St. Petersburg, writes (*Annales d'Oculistique*, September and October, 1873) to point out the objections which apply to the use of blue glasses, and the superiority of grey or smoked glasses. He argues that blue glasses will not diminish equally the amount of coloured rays which reach the retina, inasmuch as they transmit a large number of the red rays in addition to all the blue and violet; while it is essential that, in attempting to shield the eyes from too bright a light, the surgeon should employ some glass which will diminish in equal proportion all the rays which constitute ordinary sunlight. He argues entirely on the assumption that there are distinct sets of nerves in the retina which are especially sensitive to certain rays of light, and asserts that these glasses protect most completely the nerves sensitive to yellow rays, a very little those nerves which are sensitive to red rays, and not at all those which perceive the blue or violet rays. Another objection which he makes is that, after wearing blue spectacles, the eye has great difficulty sometimes in accommodating itself again to ordinary sunlight.

On the other hand, Dobrowolski has great reason for believing that smoked glasses do not entail any of these inconveniences, because they diminish the passage of all rays equally, and do not render the eye that has been wearing them unable to adapt itself to ordinary bright light.

B. J. VERNON.

HALTENHOFF ON RETINAL HÆMORRHAGE IN CASES OF DIABETES.—Dr. Haltenhoff, of Geneva (*Annales d'Oculistique*, July and August, 1873), lays stress upon the fact that more attention has been paid to the occurrence of cataract than of other affections of the eyes in these cases.

In addition to cataract there are several causes of impairment of vision, viz. :—

1. A weakness or paralysis of the accommodation ;
2. Amblyopia, slight in degree and generally transient, without any apparent intraocular lesion—in all probability due to a failure in the function of the retina through the impoverishment and general decay of the system ;

3. Amblyopia, decided in amount and incurable ; if the the patient be long-lived, terminating in progressive atrophy of the retina and optic nerves. A case of hemiopia, narrated by Von Gräfe, is considered by him due to some affection of the optic tracts, and in the cases of amaurosis with white atrophy Von Gräfe is well disposed to admit a cerebral cause.

4. Amblyopia, due to inflammation and to hæmorrhages within the retina, such as are met with in Bright's disease.

Authors of note admit the existence of such lesions, although in some at least of their cases there was albuminuria present.

Dr. Haltenhoff records a case of a woman aged twenty-nine, who was the subject of retinal hæmorrhage and peripheral retinitis, without any patches or streaks of effusion, and without albuminuria. The yellow spot was not involved, and her vision = $\frac{16}{70}$. The choroid and crystalline lens were both healthy, but the amount of sugar in the urine as shown by the polarimeter was very great. Under treatment, the patient improved so as to be able to read no. 2, Jäger, and her vision for distance improved to = $\frac{16}{20}$.

Dr. Haltenhoff asks whether there was any direct relation between the diabetes and the retinitis, or was their occurrence merely a coincidence ? If so, when the action and functions of the brain, the heart, and the kidneys were normal, wherein are we to seek the cause ? There was none to be found in her work or mode of life ; and when we see how the retina may be involved in uræmia, anæmia, lead-poisoning, leucocythæmia, or poisoning by alcohol or tobacco, and when so many different organs and tissues are affected by sugar in the blood, why should not the retina be assumed to suffer in its turn ?

In one respect the parallel is imperfect, inasmuch as diabetes does not predispose to hæmorrhage ; even the phthisis which terminates many of the cases is not so marked by hæmoptysis. Dr. Haltenhoff explains the anomaly of the hæmorrhage in these cases, by supposing an alteration in the tension of the blood-vessels brought about by the altered relations of the fluids within them.

B. J. VERNON.

WECKER ON IRIDOTOMY.—M. Wecker (*Annales d'Oculistique*, September and October, 1873), speaks of Cheselden as having been the originator of iridotomy in 1728, or at all events of having carried into practice an idea of his master, Thomas Woolhouse. The operation was then forgotten till, in 1812, Manoir in vain attempted its adoption. That there are at least two descriptions of the exact method of proceeding of Cheselden ; the one by Morand, who had seen Cheselden operate, and the other by Sharp, a pupil of Cheselden. The two descriptions do not quite agree in detail ; but it would seem that the operation consisted in piercing the sclerotic and the posterior chamber with a narrow knife, the point of which was pressed against the iris, and made to divide it as it was withdrawn. The extreme danger to the crystalline lens in this operation was obvious, and in 1756 Heurmann modified the operation by

performing it through the anterior chamber with a lance-shaped knife, the same instrument being used for the section of the iris as of the cornea—a proceeding little less dangerous.

Then came the method proposed by Guérin, in which the section of the iris was subsequent to that of the cornea, and was made, too, with a separate instrument. Lastly, Janin, in 1772, describes his plan of operating with scissors ; and it is clear from his account how well aware he was of the many difficulties and dangers which, till his time, surrounded the operation. From that time till very recently it does not appear that the many surgeons who have made trial of it have in any way added to the popularity of the operation.

It was by Von Gräfe that iridotomy was restored to its proper place ; and he advised its performance in certain cases of occlusion of the pupil after cataract extraction. His method was based on the principles laid down by Cheselden and Heurmann. At the Congress in London in 1872, a paper by Mr. Bowmann was read, advocating such an operation in some cases of corneal opacities, of conical cornea, &c., in all of which the crystalline is *in situ*. This procedure is thus described by Mr. Soelberg Wells (*Treatise on Diseases of the Eye*, 3rd edition).

Through a small conical opening made by a broad needle opposite the intended pupil, he introduces a very small knife, stout at the end and back, as far as may be necessary through the pupil, between the iris and lens ; and then turning the edge forward, he incises the pupillary edge to the extent required, using the cornea as a background against which he cuts. In doing this, the posterior surface of the cornea may be slightly incised, but any temporary subula thence resulting soon disappear. The incision made in the iris gapes and forms the new pupil, which retains some mobility under varying light.

M. Wecker considers that there is serious risk of a permanent opacity if the membrane of Descemet be wounded, and in his own method of operating he recurs to the use of scissors after the suggestion of Janin.

M. Wecker recommends iridotomy in cases in which the lens is present, and in which the new pupil is made for optical reasons ; this he calls simple iridotomy ; as also in cases where, the lens being lost, it is necessary to cut a passage for the rays of light through inflammatory products situated in or behind the pupil ; this is called double iridotomy.

The instruments required are a small lance-shaped knife provided with a stop, and a pair of scissor-bladed forceps with carefully rounded ends.

He performs simple iridotomy in cases of central opacity of the cornea or of the lens, in the following manner.

The eye being fixed in the usual way, the section of the cornea is made parallel to the iris and as nearly opposite as possible to the desired new pupil. The scissors are then introduced closed into the anterior chamber, and, after being passed carefully across the pupil, are slightly opened, so as to permit one blade to pass between the edge of the pupil and the lens. With one stroke of the scissors the pupillary edge and the circular fibres are divided, and the scissors are then withdrawn.

M. Wecker says that the after-effects are very slight and the inconvenience to the patient very trivial, while the gain in vision is most satisfactory. He adds, however, that though very simple in the hands of the practised operator, the operation should never

be attempted by the inexperienced, and cannot therefore be generally adopted.

Double iridotomy is adopted for eyes which, in consequence of an accident, have been deprived of their lens, and where the pupil has become occluded by inflammatory products. In performing the operation the section is made with the same stop-knife which is pushed through the iris as well as the cornea; the knife is to be withdrawn with great care in order to avoid any escape of vitreous humour; the iris and the membranes behind it are then cut through with the scissors. In some cases a V-shaped section is advantageous.

M. Wecker considers that iridotomy has great advantages over iridectomy and iridesis in cases where a new pupil is required for optical reasons.

BOWATER J. VERNON.

RECENT PAPERS.

Examination of the Eyes in four Schools in Wiesbaden, and comparison of the results with the numbers obtained in other places. By Dr. H. von Hoffmann. (*Klinische Monatsblätter für Augenheilkunde*, October, 1873.)

A Short Report on the most recent Attempts at Perfection in the Removal of Cataract. By W. Zehender. (*Ibid.* Nov. 1873.)

Sarcomatous Ectropion of each Conjunctiva cured by Excision of the Conjunctiva. By Dr. J. Talko. (*Ibid.*)

Sarcoma of the Conjunctiva of the Upper Eyelid: Excision: Cure. By Dr. J. Talko. (*Ibid.*)

Epithelioma of the Conjunctiva of the Bulb; Excision: Recovery. By Dr. J. Talko. (*Ibid.*)

MISCELLANY.

A MALE NURSE.—The *Philadelphia Medical Times* says that the *Lepus Bairdii* is a peculiar species of rabbit which is found in the mountains near the Three Tetons of Wyoming and the heads of the Snake River and the Missouri. One of its peculiarities is the habit which the males have of suckling the young. Numerous specimens of this sex were obtained by the naturalists of Hayden's geological survey of 1872, with well-developed teats and mammary glands filled with milk.

ELEPHANTIASIS TREATED BY RATTLESNAKE POISON. The *Philadelphia Medical Times* translates from the Portuguese (Brazilian) *Diccionario de Medicina Popular*, an account of a man, the subject of elephantiasis affecting the whole body, who, in despair of cure by other means, allowed himself to be bitten by a rattlesnake. It is a vulgar belief in many of the States of South America, where erysipelas is very prevalent, that the bite of the rattlesnake produces a certain cure without any disastrous consequences to the patient. Symptoms of poisoning, however, set in soon after the bite, and death occurred after twenty-four hours of great distress.

PRIZES OF THE ACADEMY OF MEDICINE.—In addition to the Ourches prizes, the report on which is given at page 205, the Academy of Medicine in Paris has made the following awards for 1873. The only two prizes awarded in their entirety were the Academy Prize (1,000 francs), to Dr. Puel, of Figeac, for his essay on the History of Resection of Bones in their Continuity, after Gunshot Wounds; and the Amussat prize (1,000 francs), to M. Jacques Reverdin, of Geneva, for his researches on skin-grafting. The Godard prize of 1,000 francs was divided into two portions as 'recompences'; one of 700 francs to Dr. Poncet, for his essay on *mal perforant antonin* (Dr.

Poncet also received a portion of the Ourches prize); and one of 300 francs to Dr. Felizet for his Anatomical and Experimental Researches on Fractures of the Skull. There was no award of the Itard triennial prize (2,700 francs); but a recompence of 1,000 francs was awarded to Dr. Armieux for his Medical Studies of Barèges, and one of 500 francs to Dr. Deroubaix for a treatise on Genito-Urinary Fistulae in the Female. The Portal prize (1,000 francs), the Civrieux prize (900 francs), the Capuron prize (3,000 francs), and the Barbier prize (3,000 francs), remain in the hands of the Academy; there having been no competition for the former two, and no sufficiently good essay offered in competition for the others.

BONE SCRAPING IN THE SOUTH SEA ISLANDS.—A correspondent of the *Medical Times* writes that a notion prevails there that headache, neuralgia, vertigo, and other cerebral affections proceed from a crack in the head or pressure of the skull on the brain. The remedy is to lay open the scalp with a cross or T incision, then scrape the cranium carefully and gently with a piece of glass until a hole is made into the skull down to the dura mater, about the size of a crown-piece. Sometimes this scraping operation will be even to the pia mater by an unskilful surgeon, or from the impatience of the friends, and death is the consequence. In the best of hands about half of those who undergo the operation die from it; yet this barbarous custom, from superstition and fashion, has been so prevalent, that very few of the male adults are without this hole in the cranium, or 'have a shingle loose,' to use an Australian phrase. It is said that sometimes an attempt is made to cover the membranes of the cranium so exposed by placing a piece of cocoa-nut shell under the scalp. For this purpose they select a very hard and durable piece of shell, from which they scrape the softer parts and grind quite smooth, and put this as a plate between the scalp and skull. Formerly the trephine was simply a shark's tooth; now, a piece of broken glass is found more suitable, or less objectionable (if we may even so qualify the act). The part of the cranium generally selected is that where the coronal and sagittal sutures unite, or a little above it, upon the supposition that there the fracture exists. This bone-scraping remedy is likewise employed in cases of rheumatism in old people. The cuticle is incised longitudinally, and the centre of the ulna or tibia laid bare; then the surface of the bone is scraped with glass, until a large portion of the external lamina is removed.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 15s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, APRIL 15, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

THE SIGNS OF DEATH.*

(Concluded from page 207.)

It is known that the lowest limit of temperature in disease is 32° Cent. (89·6° Fahr.) ; below that, death is inevitable. It has, therefore, occurred spontaneously to the mind of some observers to seek for a positive proof of the termination of life in the cooling recorded by the thermometer. We ourselves, thirty years ago, had made some experiments destined to determine the *maxima* and *minima* of morbid temperature compatible with existence ; and we had recommended the application of thermometry to forensic medicine.

In the present competition two distinguished practitioners, MM. Durand and Linas, have severally written interesting works on this new point of science, and the commission has awarded 1,000 francs to each of them. The first of these gentlemen has repeated more than a thousand experiments on man and animals ; the second, who has made experiments in a great hospital in Paris, has studied the variations of temperature after death, not only in man at various ages, but also in new-born children. If only the laws of calorificity in disease were taken into consideration, it might be said that, with the exception of scleroderma, an affection only observed in foundling hospitals, the lowering of the temperature to 30° Cent. (86° Fahr.) is a positive announcement of death. But as in experiments on animals, and especially in freezing experiments, it has been possible to make the thermometer fall much lower, and as also, in an hitherto unique observation on a woman who was brought in to M. Michel Péter's ward, at La Pitié, dying of cold, that physician noted down a temperature of only 20° Cent. (68° Fahr.) and life was, notwithstanding, restored by artificial heat ; we should not really be authorised to declare death certain unless the thermometer had fallen still lower, and had fallen to the figures of 25°, 22°, or 20° Cent. (77°, 71·6°, or 68° Fahr.), the extreme limit beyond which frozen animals have not been able to be reanimated.

But if we ought to expect that the column of mercury would fall so low after death, the thermometer would be of slight assistance ; since eighteen to twenty-four hours are needed for the corpse to enter into equilibrium with the surrounding temperature, and since thus in summer, in very hot days, the temperature of the dead body remains the same as the atmospheric medium and cannot fall below 25° Cent. (77° Fahr.).

For these reasons, we think that a positive sign of death should less be sought in an absolute and deter-

minate cooling than in the gradual refrigeration which commences at the first moments of death and goes on increasing. The body loses about 2° Cent. of heat every hour, so that after three or four hours have passed the temperature has generally fallen to 32° (89·6° Fahr.) or even to 30° (86° Fahr.) ; at this point of morbid refrigeration the torch of life, after having emitted a fainter and fainter light, goes out for want of fuel.

It will be seen that the studies induced by the Ourches prize of 5,000 francs, which has been divided with justice (and the commission regrets not to have more rewards at its disposal), give a still greater certainty to the signs before indicated as announcements of death, and they add others which are of greater value.

Besides, it must be remarked that the question of the certainty of the signs of death is not an affair of theory but of practice. It does not concern the physician to discover a characteristic sign of the extinction of life, and may be an unequivocal sign according to which he decides ; an abstraction made from all the others, and from the mutual help they afford each other. Life has been defined as the assemblage of functions which resist death. What then can death be, except the end of the resistance in the whole of all the functions, an end which, to be affirmed with certainty, should be studied everywhere ; separately as well as in the organic whole ?

Practically, and as a matter of fact, what is this problem ? It is to distinguish a dead person from a living one. And besides, it is not at the moment when the final struggle is finished, a struggle which has often been retarded by the skill or the tenderness of the family, it is not at the end of a few hours only that the verifying physician is called on to pronounce his judgment ; it is after ten, fifteen, or more hours, since the law which protects us above all against criminally hastened inhumations prescribes a delay of twenty-four hours, which is frequently exceeded. It will be acknowledged that, after all these hours have passed away, verification is easy for the physician who ought at all times and everywhere to replace the civic official. He may with equal security to his conscience as to the uneasy anxiety of the relatives, confirm the inexorable decree by his signature. Yes ! modern science can assign to real death the indispensable stamp of the most absolute certainty, and it gives the most certain guarantees against the danger of premature interment.

There is another irrefragable sign indicated in M. Bouchut's *Traité des Signes de la Mort*. The winner of the Manni prize in 1848 makes a happy application of Laennec's admirable discovery furnished by auscultation of the heart. In the human machine the heart is, properly speaking, the pendulum of life ; so long as this pendulum oscillates, so long as its movements and its sounds are perceived by the ear applied to the breast, existence continues ; it ceases with their disappearance. M. Bouchut only asked for five minutes of observation in the cardiac region, to ascertain by the stethoscope that death had occurred ; the commission of the Institute wished that no decision should be arrived at before a period fifty times as great, that is to say, before at least four hours, which is a very long time. It may be affirmed that half-an-hour of stethoscopic examination will suffice for a medical man ever so little used to auscultation, on condition, however, that this examination should not be made until several hours after the presumed death. The con-

* Report on the prizes founded by the Marquis d'Ourches for the discovery of a simple and popular means of recognising the signs of death.

clusion is then absolute, infallible. So long as the heart speaks to the ear by its contractions there is life; if it be definitely silent, death is certain.

We will now give some details respecting the prize of 20,000 francs, destined by the Marquis d'Ourches for the inventor of a sign of death which shall be within the comprehension of a poor, uneducated villager. Many candidates for it have presented themselves, not only from Paris, not only from twenty different departments, not only from Europe, but from the East, from America as far as Chicago. Some medical men are comprised in this catalogue, but a much larger number consist of inventors without any medical title, nobles and workmen, retired military men and benefited clergy, priests, pastors, and rabbis, public functionaries, schoolmasters, tutors, women, some tradespeople and merchants, a small grocer living in the Gard, and finally one competitor who may be supposed to be a hairdresser, for he says he can recognise death by the hair; only he demands the prize offered to him to buy his secret. What serious work could be looked for in this motley assemblage? What lucubrations could emanate from the brain of these persons ignorant of every scientific fact, who have had the pretension to unveil the mysteries of life and death, and have believed themselves capable of resolving, like Hamlet, the question of 'to be or not to be'? All these efforts could only end in absurd or dangerous processes for the verification of death.

For instance, one proposed an instillation of ammonia into the eye; the other burning on the temples or the region of the heart with an iron heated to white heat; this one recommends injection of strychnine into the stomach; another, an incision in the heel sufficiently deep to reach the fibres of the little toe. One, a German, proposed to magnetise the subject; another to place a strong reflector before the eye, so as to cause contraction of the pupil. This one extols his apparatus for registering movements; that one his spring coffin; another recommends that a ladder should be placed near the coffin, so that the resuscitated person may be able to get out of it; another recommends the placing of a bell-rope in the hands, and a trumpet in the mouth of the corpse.

As a matter of course, the academical commission could not reward any of those strange methods of verifying death, nor many other proceedings, notwithstanding that, strictly speaking, they might be put in practice by ignorant villagers. It consequently decided that there was no reason for awarding the Marquis d'Ourches' great prize. However, it had hoped at one time to be able to award the prize. The competitor was a professor of forensic medicine in a German university. He gave as a constant and infallible sign of death the parchment-like state of the skin at the points where friction had been made with a hard body some hours after death. The implement, a wet brush, is simple; the application, friction for some minutes, easy; and the judgment easily made: the skin in the region rubbed ought to have the appearance of parchment. The commissioners, however, have repeated the experiment on several occasions, and the promised result has seldom appeared. However, as on the one hand, the labour of the learned professor rests on numerous experiments; and as, on the other hand, in the competition instituted by the learned societies equity demands that nationality should be considered as an abstract matter, the

Academy is happy to grant M. Weber, professor at Leipsic, a very honourable mention. The sum of 20,000 francs, left conditionally to the Academy by the Marquis d'Ourches, not having been employed, returns to his heirs. It should soften the regret of the aspirants to the non-awarded prizes to know that the heirs of the Marquis are the poor of the town of Saint-Germain.

The Marquis d'Ourches was a singular but a very sympathetic personage; his life, like his character, displays every imaginable contrast. He belonged to the oldest nobility of France, the family of Ourches having been doubly allied to the ancient dukes of Lorraine. Heir to an illustrious name, he was the last of his race, and died alone and unknown at Batignolles.

Born a marquis, he became a simple workman, and from that time forward he wore the costume all his life. He had a great fortune. The year 1793 despoiled him of it. Escaping the scaffold at the revolution, and a prison under the empire, he contributed by personal exertions, and from his diminished means, to the restoration of the monarchy; but in the midst of all these changes the fortune of his ancestors had melted away, and at the end of his resources the Marquis d'Ourches came to gain his daily bread by helping plumbers, at a wage of sixpence a day. Fifteen years passed thus in poverty, supported in a dignified manner. The labourer rose in grade and became a glass-blower, a worker in glass for scientific instruments, then a skilful constructor; by this hard work, the fallen aristocrat reconquered his titles of nobility.

In the last years of his life the Marquis d'Ourches occupied himself with somnambulism and spiritualism, for which he had the means, an inheritance from the maternal side having placed him in easy circumstances. He tampered much with the so-called spirits, though he sometimes said he found '90 per cent. of juggling amongst them.'

He also gave himself up to experiments in crossing, acclimatising, and even taming animals; he lived on familiar terms with widely differing animal races, endeavouring to accustom dogs, cats, rabbits, deer, horses, tigers, and men to live together in peace and harmony.

The Marquis d'Ourches was always a noble-hearted man; when he was rich, he spent his fortune with his brilliant companions in arms in pleasures to which he largely contributed; when he was poor, he shared his little modicum with his fellow-workmen; and when prosperity again returned to him he never forgot these last, these true friends of his humbler days. He told the Mayor of St. Germain that he always kept at his disposal three or four hundred thousand francs for the construction of an hospital at St. Germain, and he has kept his promise posthumously.

'I have seen death in every aspect,' said a general to Doctor Josat, one of the gentlemen rewarded by the Institute for a book on mortuary houses, 'and it has never had any terrors for me, but I own that I shudder at the notion of finding it at the bottom of a ditch in the cemetery.' The Marquis d'Ourches, brave in all other things, had the same fears of a premature interment. He kept a record of all the stories of underground resurrections; he believed in them, and even asserted that one of his uncles had been buried alive. Hence the foundation of the academic prizes of which we have just set forth the results. This posthumous liberality displays the

complete disinterestedness of the Marquis d'Ourches in a strong light ; he promises a large reward to the inventor of an infallible method of verifying death and preventing premature interment, notwithstanding his knowledge that this proceeding, to be discovered long after his death, could not profit himself in the least.

MACLEAN ON THE SPIRIT-RATION IN THE BRITISH ARMY.

In a recent lecture at the United Service Institution, Surgeon-General Maclean, C.B., made some authoritative but startling statements on this subject which deserve to be very carefully considered. He said : ' If there be any point of military hygiene that may now be regarded as settled beyond doubt or cavil, it is this, that spirits are not only not helpful, but are hurtful to the marching soldier, everywhere I believe, but nowhere more so than in hot climates. The evidence on this point is overwhelming. The medical officers of the French army, who have had great experience in the arduous campaigns in Algeria, denounce the spirit-ration as hurtful ; and Dr. Morache, already quoted as a high authority on military hygiene, declares that, unless coffee had taken the place of spirits, it would have been impossible for the troops to surmount the fatigues of what he justly calls *ces pénibles campagnes*. Were I the medical chief of an army destined to take the field in a tropical climate, not a drop of spirits should, with my consent, accompany it, save what the requirements of the ambulance service demanded. The evidence shows that wherever soldiers, by accident or design, have been cut off from the use of spirits on marches, on active service, in temperate climates exposed to wet and cold, or in the tropics to ardent heat, or in laborious sieges, they have maintained their health, spirits, and discipline far better than when the once-deemed indispensable grog was in daily use. My colleague, Dr. Parkes, and the late Count Wollowicz, in a series of careful experiments on the use of alcohol carried on at Netley, and published in the *Transactions of the Royal Society*, have placed on a sure scientific basis what was before a matter of observation, and have established that alcohol, far from increasing the power of bearing fatigue, even when given in a quantity which many spirit-drinkers would deem within the limits of moderation, lessens muscular force ; and a quantity in excess of this, it was shown, entirely destroyed the power of work. The reason, Dr. Parkes says, was two-fold. There was, in the first place, *narcosis* and blunting of the nervous system—the will did not properly send its commands to the muscles, and the muscles did not respond to the will ; and secondly, the action of the heart was too much increased, and induced palpitation and breathlessness which put a stop to labour. The inference was, "that even any amount of alcohol, although it did not produce symptoms of narcosis, would act injuriously by increasing unnecessarily the action of the heart, which the labour alone had sufficiently augmented." For fatigue, rest and food are the proper remedies. Alcohol given alone under such circumstances can only stimulate the already nearly exhausted heart to fresh exertion. Under some very exceptional circumstances it may be a matter of absolute necessity to do this ; but even then we must follow Dr. Parkes's rule—namely, to give spirits in small quantity, not more than an ounce of brandy, and if possible it should be

mixed with Liebig's meat-extract, which has a great power of removing the sense of fatigue. Dr. Parkes even gives a formula, which is worth bearing in mind, for use under such circumstances ; as for example, when troops, after a fatiguing march, are obliged to engage the enemy without time for rest and food, he advises two ounces of red claret wine, with two teaspoonfuls of Liebig's extract, in half a pint of water. Wine not being available, half an ounce of brandy or rum would be a good substitute.

' It is almost superfluous to add, that the best substitute for alcohol is coffee or tea. The French military medical officers vaunt, and with justice, the superiority of the light wines of their own country over the more strongly brandied wines of Spain and Portugal ; and they point to the fact that, when used in moderation, the aromatic principles and the various salts they contain exercise an effect on the digestive organs which is alike wholesome and agreeable. With all this, the best of them give a decided preference to coffee. Morache, in particular, is emphatic in his testimony, and is even eloquent in its praise as an article of diet, a safe stimulant, an aid to digestion, and an efficient refreshment under fatigue. Coffee forms no part of the ration of the French soldier in time of peace ; but Morache does not hesitate to urge its issue instead of brandy, and he instances certain regiments in which the custom of substituting coffee for the morning *petit verre* had much advanced the cause of temperance.

' That a cup of hot coffee is the best preparation for the fatigues of a march is indisputable, and it should never be omitted. It is much better that the men should have it before leaving their ground, and not at the half-way halt, as was common in my time in India : it invigorates them at starting, protects, particularly the young soldiers, against the gripping abdominal pains to which they are subject, particularly in the dark and chilly hour preceding the dawn ; and the vigour it imparts helps the system to resist the miasm which at this hour is most freely evolved from the soil. It is worthy of remark that coffee was first issued to European troops for this very purpose, on the advice of the great Larrey, during Napoleon's Egyptian campaign.

Professor Maclean mentioned an instructive example of the mischief of spirit-rations served out in hot climates. The troops holding Canton were called on to turn out at midday. A battery of artillery had more cases of insolation than all the rest of the force put together, the reason being, that the canteen was opened by the officer commanding with the 'good intention' of 'fortifying' his men with a glass of grog before starting. Staff Surgeon-Major Becker, an accurate observer, and in this case an eye-witness, was Professor Maclean's authority for this pregnant fact.

FORENSIC OPHTHALMOLOGY.

ON INJURIES OF THE EYE IN THEIR MEDICO-LEGAL RELATIONS. BY PROFESSOR ARLT, OF VIENNA.*

(Continued from page 211.)

If the globe be flattened in the region of the anterior pole (and this is what most frequently occurs), the equatorial diameter must be increased ; at

* *Wiener Medizinische Wochenschrift*, March 7 and 14.

least when the globe at the posterior pole is pressed against the elastic cushion of fat. The dilatation will reach its maximum in the equatorial zone, but will still be considerable on both sides of it. The choroid is, so to speak, inseparably united in front to the corneo-scleral ring by the ciliary muscle (Brücke's tensor choroideæ) and behind to the point of entrance of the optic nerve; between, it is very loosely connected with the sclerotic, and is, indeed, easily removable. At about the middle part, between the above-named inseparable connections, that is to say, where the vasa vorticosa pass to the sclerotic, the two membranes are firmly connected for some extent, not only by the vessels, but also by firm dense connective tissue. The range of close union of these structures is extended by the passage of vessels and nerves near their anterior connections, and by the passage of the large ciliary arteries from the sclerotic into the choroid, around the optic nerve, and especially in the neighbourhood of the posterior pole. If now, through the flattening of the globe, the equatorial zone of the choroid be pressed in the direction of its periphery, while the pressure of the vitreous humour on the retina and choroid remains the same, the pressure will bear on a small portion of the choroid, the resistance of which may be readily overcome; and thus there are produced rupture of the vessels and tissues, and the rents in the tissues must run concentrically to the posterior pole.

Rupture of the vessels may also probably occur in an analogous manner in the neighbourhood of the anterior fixed part of the choroid; direct evidence of this, however, is only obtained after death. Rents in the choroid in front of the equator have, hitherto, however, been observed only in cases where the globe has been acted on by a blunt object. Here the rent of the choroid can be explained by a crack in the sclerotic at this part, just as also many hæmorrhages from the ciliary bodies may be referred to the crushing of the vessels by the rebound of the sclerotic at this part. The laceration of the choroid further backwards, also concentrically to the periphery of the optic papilla, may be traced without doubt to the dragging forward of the portion of choroid lying posteriorly.

Most difficult, without doubt, is the explanation of the lacerated wounds which are observed after a blunt force has acted on the anterior zone of the sclerotic, and which not only affect the sclerotic, but always extend through the uveal tract. It is remarkable that these wounds, through which more or less of the fluid contents of the globe, even a portion of the iris, and perhaps also the whole lens, are instantly protruded, run quite or nearly concentrically to the edge of the cornea, and almost without exception occur above, generally also to the inner side.

In opposition to the opinion of Zander and Geissler (*Injuries of the Eye*, 1864, p. 373) that the globe comes into contact at the lower or lower and outer part with the sclerotic, and above, or above and to the inner side, with the orbit, where it meets with an invincible resistance, in consequence of which the sclerotic is lacerated, and the lens escapes (when violence is offered in this direction) Manz (*Klinische Monatsblatt*, 1865, p. 177) says, 'It is to be observed that it is not the two points of the eye which are directly pressed on, the one by the instrument, the other by the unyielding wall of the orbit, that may be lacerated; this will take place at a relatively free

part, where, while the distension is greatest, the cohesion (or more correctly, the support) is weakest; and this is the portion of sclerotic lying next to the inner and upper border of the cornea.' If it be assumed that large foreign bodies cannot well strike the eye except from below, or from the lower and outer part, and that the eye at this moment is turned upwards, or upwards and inwards, the blow falls generally at the lower, or lower and outer part, on the sclerotic, between the edge of the cornea and the equator of the eye; and the rupture will take place at its least supported point, nearly midway between the part where the force is applied and the opposite point. But if the blow fall on the upper and outer part of the anterior sclerotic zone, as in the case observed in Ruete's clinic, published by Schröter (*Klinische Monatsblatt*, 1866, p. 245) laceration of the sclerotic and uvea takes place at the lower and inner part. That the rent on the sclerotic is almost without exception concentric with the border of the cornea, may fairly be attributed to the fact that the fibres of the sclerotic in the region of the ciliary zone have mostly a concentric arrangement.

Ruptures in the region of the iris (especially iridodialysis) are explained without difficulty by the widening of the corneo-scleral ring through the flattening of the cornea; the ciliary muscle, and not the iris, being firmly connected with the ring. Rents of the iris in a radiating direction depend on pressure of the lens on the iris at the same time that the cornea is flattened, the pupil being contracted.

Distension or laceration of the zonula and rupture of the anterior (or posterior) capsule, and the consequent change in the form and position of the lens, may in many cases be attributed to the sudden widening of the corneo-scleral ring; but in fact they occur also without any such widening, especially in simple concussion of the eye.

No sufficient explanation can be given of the paralysis of the sphincter of the iris and of the accommodation-muscle, until the obscurity attending the so-called commotio retinæ shall have been gradually cleared.

In most of the injuries belonging to this category, the change produced is not in proportion to the force applied, and is rather to be regarded as the product of 'the special condition of the body' (the eye) and of the act of injury. Not only age with its increased fragility of tissue, but also the state of refraction (a higher grade of short-sightedness), and pre-existent though unnoticed ectopia of the crystalline lens, may have much weight in the causation of the injury. The more or less superficial or deep position of the globe must, among other things, be also taken into account.

2. A very frequent result of the impact of a blunt body on the eye (on the lids or edge of the orbit) is effusion of blood under the conjunctiva bulbi, in the loose subconjunctival connective tissue. This, although perhaps limited at first, may, under the influence of coughing, sneezing, &c., attain such extent and thickness that the more or less dark red and distended connective tissue projects partially or entirely round the cornea like a wall. The appearance of subconjunctival ecchymosis some days after the accident, gives rise to the suspicion that the injury has produced effusion of blood deeply within the orbit.

Diagnosis, Prognosis, and Treatment.—The temporary disfigurement, and perhaps compression or distension, are in themselves of no importance. But

a careful testing of the function of the eye, and, when this is not satisfactory, an ophthalmoscopic examination, are necessary, since changes may take place in the interior of the eye or behind it. The blood is reabsorbed in a few days or weeks; a yellow tinge may remain for some time, or, when there is deeply seated effusion of blood, may first appear after some days. The diagnosis from the chemotic swelling of the connective tissue which attends inflammation is furnished by the absence of other phenomena of this process, which indeed must be very intense before it can produce a blood-red wall around the cornea.

In some cases, the formation of subconjunctival cysts has been observed as a result of contusion.

Cold-water dressing, with or without the addition of spirit, or perhaps with tincture of arnica, and avoidance of all causes which impede the return of blood to the superior vena cava, are to be recommended. Incisions are scarcely ever necessary.

3. A blow on the cornea from a relatively small body, which, however, penetrates its substance but little or not at all, very often gives rise to inflammation and suppuration of the cornea; generally in the form of abscess, more rarely of ulcer. This is one of the most dangerous forms of inflammation of the eye.

A second person is rarely concerned in the production of this injury; it is generally due to accident or to the imprudence of the patient, and may arise from the impact of a piece of metal, stone, or wood, a straw or ear of corn, &c. Whether this result may follow when the contusing body comes into contact only with the lid and not directly with the cornea, is not ascertained with accuracy.

This keratitis occurs with greater relative frequency in old than in young subjects, and hence one is justified in ascribing a 'special disposition' to advanced age. Discharge from the lacrymal sac is moreover so often found in persons with corneal abscesses, that one cannot avoid ascribing a part of the subsequent mischief to this complication. In connection with this, the advice is sound, to at once remove or diminish the lacrymal obstruction by dividing the lacrymal canal and introducing a cannula; and to first remove the obstruction in cases where an operation is necessary. The mischievous influence of lacrymal obstruction in the cornea when wounded, is rendered certain by the statistics of operations for the removal of cataract.

Diagnosis.—At the point involved there are developed zone-shaped ciliary injections around the cornea, and an orbicular dull light-grey opacity, which afterwards assumes a yellow colour in proportion to the amount of pus lying behind it in the cornea.

If the corneal abscess be seen for the first time when a portion of the pus is removed, its edges are more or less swollen and very opaque, while the centre is unequally grey and more or less sunken. It may then be doubtful whether it is an ulcer or an abscess that is seen; but this is of no practical importance, since in both cases extension towards the periphery is most to be dreaded. This extension (the 'ulcus cornea serpens' of Sämisch) may take place even after the cessation of all other symptoms of inflammation (ciliary injection, pain, photophobia, and lacrymation), and occurs in an upward or lateral direction as readily as downwards. An ominous forerunner of this extension is a light grey halo around the focus of suppuration.

Along with the suppuration in the cornea, more or

less pus is almost without exception found in the anterior chamber; sometimes almost imperceptible from its sinking behind the corneo-scleral fold, but not unfrequently filling half or two-thirds of the chamber. The occurrence of irido-cyclitis may also give rise not only to a moderate collection of pus, but also to severe pains, lasting day and night, the only effectual remedy for which is to open the anterior chamber.

Prognosis.—An abscess leaves at least an irremovable and more or less complete opacity, which injures sight sometimes through reflection, sometimes through diffusion of light, according as (which is generally the case) the abscess first affects the middle region of the cornea, or extends into it. Even when the patient is placed in the best condition, and the treatment is most correct, the cornea may be so far destroyed that no good can be expected from iridectomy. The further results of extensive or total corneal suppuration (staphyloma, phthisis bulbi, &c.) it is not necessary to discuss here.

Treatment.—Cold compresses may be applied with advantage immediately after the receipt of the injury; but, when suppuration has set in, they are useless, and, instead of them, it is generally advisable at an early period to apply lukewarm chamomile fomentations. The patient should not be allowed to go about; atropia should be dropped into the eye; both eyes should be protected from brilliant light, and the injured one covered with charpie, applied more or less firmly. In most cases, the application of moist heat for ten or twenty minutes several times a day, with the charpie in the intervals, will arrest suppuration. If in the course of one or two days it become evident that suppuration is taking place, and the pus have accumulated in the chamber as high as the edge of the pupil or above it, or if the patient suffer severe pain, an operation ought not to be delayed. The best proceeding is that recommended by Sämisch, of Bonn.

The patient should be in bed, as in many cases the operation is followed by severe, if not long-continued pain; and the patients often faint. The operation is generally performed without anæsthesia. The eye being well fixed, a Gräfe's knife, with its edge directed forward, is introduced into the healthy cornea at the edge of the purulent collection, is pushed into the chamber behind the abscess, and carried to the opposite edge, so that the counter-puncture lies as much as possible in healthy tissue. The incision is then completed by making small and slow cuts from behind forward. The cut should be straight, and should be in the greatest diameter of the corneal bulging. A sufficiently extensive incision cannot be made with a lancet, which has to be depressed at once so as to avoid injury of the iris or capsule. The aqueous humour escapes slowly. The pus in the chamber is not removed by the surgeon, but is left to be absorbed. In many cases, after the escape of the aqueous humour, lumps of pus hang out of the wound, and may be removed by forceps.

The patient should lie quiet on his back for an hour or two after the operation; atropia is then dropped on the eye, and a protective bandage applied. If the pupil do not soon become dilated, the atropia must be repeated every two or three hours. At intervals of twelve or twenty-four hours, a fine probe or a Weber's lacrymal knife is carried through the wound, until a decided decrease of the purulent infiltration and a clearing of the part has set in and continued. The continuance or reappearance

ance of masses of fibrinous exudation behind the purulent collection also indicates that the wound should be opened, or renewed at some point. A distinct and steadily advancing improvement may at once follow the simple opening up of the wound; but sometimes the proceeding has to be repeated ten or twelve times. In a large number of cases treated in this way, notwithstanding that every care is taken both by the patient and by the surgeon, vision is lost. It appears that the failure is attributable to the changes arising from iridocyclitis, which is indicated by the presence of a wide dark red zone around the cornea, and increased tenderness on touch.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

DANIS ON A CERTAIN AND IMMEDIATE SIGN OF DEATH.—The following abstract presents the researches and conclusions of Dr. Leon Danis upon this subject. Our signs of real death are at present either the immediate or probable, or the later or certain. The immediate signs of death have all been proved to be vague; the certain sign, putrefaction, admits of no doubt, but waiting for this precludes all use of means of resuscitation.

In searching for a certain sign of death it may be premised that the brain, the heart, and the lungs are the tripod of organs on which depend all vital processes, and the failure of the influence of one of which is necessarily followed by the failure of that of the others, and death follows necessarily; thus it is correctly said that one may die by the brain, the heart, or the lungs. In order, however, to ascertain the death of the brain or lungs alone, some expensive experiment is required; but in the case of the heart there is not any difficulty. We can learn whether the heart lives, sleeps, or is dead, by the state of the arteries; not, however, by ordinary observation of the pulse.

The plan proposed by Dr. Danis is the denudation and section of the artery—by a surgeon. This axiom is laid down by Dr. Danis, and will not be disputed by physiologists. *'The artery empty, the heart is dead; the heart dead, the whole body has ceased to live.'*

The great advantage to be derived from the employment of this sign is, that the emptying of the arteries must be simultaneous with death, and if it be present, attempts at restoration should be abandoned as the patient is a corpse. If this phenomenon be not present, the attempt to restore life may yet succeed.

The temporal artery, by reason of its nearness to the surface, may be selected for the operation, as also for the slight degree in which it retracts. When the artery has been exposed, its colour should be observed; after death it becomes of a yellowish or orange colour; during life it has the colour of surrounding textures. Its pulsations, if any exist, may then be observed; but it may be noted that the sudden exposure to the air sometimes stops the pulsations; from this, however, it will soon recover, if life be not extinct.

In the dead body, the artery will gape when divided, and little or no blood will flow, other than a few coagula. If the blood should flow by jets, a compress will restrain it.

If it be objected that the patient may be too feeble

for the heart to propel the blood, then it follows that it is too feeble to supply the brain with blood, and death must follow.

W. B. KESTEVEN.

SLAVJANSKY ON THE RETROGRESSIVE CHANGES OF THE EPITHELIAL CELLS IN THE SEROUS LAYER OF THE OVUM OF THE RABBIT.—K. Slavjansky (Ludwig's *Arbeiten*, vol. vii.) describes the degeneration, called by him reticular ('reticulare degeneration'), which the epithelial cells of the serous layer of the ovum undergo in their physiological development. During the development of the ovum, the epithelial cells of the part of the serous layer lying close to the umbilical sac become thin and flat, and in the cells themselves some transparent spots are to be observed. By-and-by the protoplasm disappears, and holes are observed in the cells. These holes gradually enlarge, so that, at last, in place of the epithelial membrane there is to be seen a reticulum of the remains of the protoplasm of the epithelial cells, containing in some places the nuclei. There is thus established a physiological prototype for the pathological degeneration of the epithelium, described by Wagner under the name of fibrinous degeneration, in cases of croup and diphtheria.

W. STIRLING, D.Sc., M.B. (Leipzig).

HELLER ON THE BLOOD-VESSELS OF THE SMALL INTESTINES.—A. Heller (Ludwig's *Arbeiten*, vol. vii.) arrives at the following results.—1. Every villus contains an artery which runs, as a general rule, to the point of the villus without branching. In man only does it begin from the middle of the villus to lose itself in a capillary network. 2. The vein begins either in the point of the villus (rabbit, man) or near to the same (rat), and generally goes directly into the submucous tissues without receiving any lateral branches; or it rises near the base of the villus and receives more or less numerous lateral branches from the glandular layer (dog, cat, pig, hedgehog). 3. In none of the animals examined was there to be found the often cited arrangement of an arterial stem going to the point of the villus, and of a descending venous stem with a simple connecting capillary network between both stems. This is of importance with regard to the erection of the villus.

MEDICINE.

CALASTRI ON A CASE OF SUPPURATIVE HEPATITIS FOLLOWED BY EMPYEMA.—Dr. Luigi Calastri, of the civil hospital in Milan, relates the following interesting case in the *Gazzetta Medica Italiana-Lombardia* of February 7.

The subject was a man named Giovanni Barzoni, aged thirty-eight. There was no special family history of disease; and up to the age of thirty-six he enjoyed good health. At that time, he began to suffer from loss of appetite, difficult digestion, epigastric pain, and habitual constipation alternating with diarrhoea, attended with pain in the abdomen. These symptoms returned three or four times in the year, and were treated by the patient himself with purgatives, &c.

In November, 1872, having had an attack of the above-named symptoms in the preceding month, which passed off under his usual treatment in a few days, he was seized with violent pain in the epigastric

region and abdomen, and was obliged to call in medical aid. He stated that the pain chiefly affected the right hypochondrium, and that for three days his skin had been yellow, though, after the use of purgatives, it was less so than at first. The pain in the region of the liver spread to the corresponding shoulder-blade; his digestion was difficult and painful, and he had nausea, meteorism, and constipation alternating with painful diarrhoea. He was treated with purgatives, leeches to the right hypochondrium, antimonial powders, etc.; but as no relief was produced, he was admitted into hospital on February 20, 1873.

On admission, he was visibly emaciated, and had an icteric tint; decubitus was easiest on the left side. The cerebral functions were normal; he complained of slight headache, and loss of appetite; his tongue was entirely covered with a yellowish white coating, and his breath was fetid. The form and movements of the chest were normal; respiration 17. Anteriorly, the chest was unusually resonant, as far as the upper border of the fifth right rib, where liver-dulness commenced, and extended two finger-breadths below the lower border of the ribs. On the right side, splenic dulness commenced at the eighth rib in the axillary line. Auscultation of the heart revealed nothing worthy of note.

The right hypochondriac region was the seat of severe and continued pain. On gentle palpation, the edge of the liver was found to be thickened and painful towards the left part, which was found on percussion to pass beyond the sternal line; on the right, the pain was limited within a line drawn through the nipple. The abdomen was tense, tympanitic, and painless on palpation, however deeply applied; the bowels were open; there was no œdema of the lower limbs. The patient did not appear to have been addicted to drink. The pulse varied from 80 to 90; the urine was scanty, of a greenish brown colour.

On the 21st, ten leeches were applied over the right hypochondrium, and soda lemonade was given. Next day, however, the pain had increased in severity, and the patient was very restless. Local blood-letting was again employed, with great relief; but, in the middle of the day, he had an attack of shivering, followed by heat, and by abundant sweating, which continued through the night. Next morning, he felt better; the physical signs remained just as before; the urine was not albuminous, but contained abundance of bile-pigment. The aguish paroxysms having recurred, cinchona and quinine were given, but without effect; and on March 1 he had a more severe paroxysm than before. After this, the attacks became more frequent; the skin was intensely jaundiced; there was some difficulty of breathing, with impairment of the movements of the chest on the right side, where the vesicular murmur was weakened.

Dr. Calastri arrived at the conclusion that the case was one of suppurative hepatitis, and that the attacks of rigor and heat were dependent on the formation of pus, and not on malaria. There was no splenic tumour; the paroxysms were irregular and frequent, and the sweating was profuse and of long duration.

On March 9, after a severe attack of rigors, followed by heat and prolonged sweating, he vomited some watery mucus; this was followed by a persistent cough, without expectoration. In the afternoon, he complained of pain in the lower costal region of the right side; nothing, however, was discovered here

by physical examination. On the 13th, percussion of the chest anteriorly indicated dulness on the right side from the fourth rib downwards; the respiratory sounds were indistinct, and the vocal vibration impaired; the patient felt sleepy, and there was a miliary eruption in the upper and anterior part of the chest. On the 14th, the signs of effusion in the pleura increased, and Dr. Calastri concluded that there was empyema from extension of the inflammatory process to the chest. He considered, however, that, under the circumstances in which the thoracic effusion had occurred, paracentesis of the chest was not advisable. The patient fell into a state of unconsciousness, and died on the 16th. At no time had any fluctuation been felt in the region of the liver.

At the necropsy, which was made fifty-two hours after death, the right pleura was found to contain about two quarts of sero-purulent fluid with whitish flocculi. The costal pleura near the base was covered with a false membrane of recent formation. The peritoneum contained a small quantity of serum. The stomach and intestines were distended with gas; there were some follicular ulcers in the large intestine, with partial redness and thickening of the mucous membrane. The pancreas was healthy, and the bile-ducts were free. The liver was enlarged by more than one-fourth; its convex surface was adherent to the diaphragm, and here there was found an abscess of the size of a hen's egg, containing thick yellowish pus, and lined with a dense 'pyogenic' membrane. Other small abscesses were also found in the substance of the liver, which was in a state of incipient fatty degeneration. The gall-bladder contained a little thick bile, the kidneys were rather hyperæmic.

The case was then one of suppurative hepatitis, with consecutive extension of the disease to the diaphragmatic pleura on the right side, sero-purulent exudation, and catarrhal colitis. A. HENRY, M.D.

DE RENZI ON RHEUMATIC PARALYSIS OF THE LARYNX.—Professor De Renzi relates in the *Liguria Medica*, 1874 (quoted in *Gazzetta Medica Italiana-Lombardia*, February 28), the case of a servant maid, aged seventeen, who, in consequence of a severe cold caught a little before Christmas, had cough, sore throat, and afterwards aphonia. When she was examined on December 31, the pillars of the fauces, the velum pendulum palati, and the back of the pharynx, were considerably reddened. Laryngoscopic examination showed redness of the entire laryngeal mucous membrane, and especially of the vocal cords, which remained immovable when she attempted to speak: there was no ulceration. She had slight transient headache, a sensation of a ball in her throat, and was easily excited. The diagnosis was, rheumatic paralysis of the larynx, with slight hysteria. Hydrotherapeutic treatment being without effect, faradisation was applied on January 1, to the skin over the larynx, by the electric brush. The next morning, on awaking, she was able to speak, though with a rather muffled voice; and the ability to speak remained till the evening of the 7th, though the electricity was not again applied. On that day, the fauces were found to be slightly reddened: but there was as much redness of the vocal cords as on the first day. On the 8th, she awoke in a state of aphonia; but the voice returned after the application of electricity, and remained normal up to the 16th, under daily faradisation of the skin.

This case, Dr. De Renzi says, suggests two im-

portant considerations. 1. In rheumatic paralysis of the larynx, it is admitted by many that the laryngeal muscles are paralysed through hyperæmia and collateral œdema, dependent on catarrh of the mucous membrane. In the present case, the paralysis was quite independent of the catarrh, since the former disappeared twice, while the latter remained. And it may be supposed that the same cause produced catarrh by its action on the mucous membrane, and paralysis by its action on the laryngeal nerves. 2. The statement of Bruns, Mackenzie, Eulenburg, &c., that laryngeal paralysis requires to be treated by the direct application of electricity to the muscles of the larynx by means of the laryngoscope, is not correct. In the case related, cutaneous faradisation caused the paralysis to disappear with astonishing rapidity. A. HENRY, M.D.

NOTHNAGEL ON THE DIAGNOSIS AND ETIOLOGY OF UNILATERAL INDURATION AND CONTRACTION OF THE LUNG.—Professor H. Nothnagel, in a clinical lecture on this subject (*Volkmann's Sammlung Klinischer Vorträge*, no. 66) mentions some interesting points in connection with physical diagnosis. He confines his remarks entirely to those cases in which the induration and contraction involve the whole of one lung, excluding all partial contractions. The most important elements in the diagnosis of this condition are stated to be derived from the inspection and palpation of the thorax. After describing at some length the well-known deformity of the thorax which is produced by the shrinking of the lung, and insisting upon the fact that there is complete absence of inspiratory expansion on the affected side, he alludes to the situation of the cardiac impulse. The heart is always displaced. When the left lung is affected, the impulse is usually higher and more to the left than natural, although in some cases there is no lateral displacement. When the disease is on the right side, the cardiac impulse is often imperceptible, the organ being covered by the enlarged left lung; if, however, the retraction be very considerable, the impulse may sometimes be discovered in the fourth right intercostal space, close to the sternum.

Another important sign of unilateral shrinking of the left lung is the existence of a distinct systolic impulse in the second left intercostal space, from four to eight centimètres (about $1\frac{1}{2}$ inches to 3 inches) from the left border of the sternum. This is associated with a diastolic shock, which is perceptible to the hand in the same situation. These two signs, although by no means constantly met with, exist in a large number of cases, and when they are present, Nothnagel considers them as the most certain evidence of shrinking of the left lung. In explanation of their production, they are stated to be caused by the pulmonary artery; the systolic impulse being due to the distension of this vessel during the systole, the diastolic shock to the forcible closure of the pulmonary sigmoid valves. Similar phenomena may, however, occur in other diseases in which there is increased pressure in the pulmonary artery—e.g., in mitral stenosis and insufficiency; but in such cases the pulsation is much nearer to the left border of the sternum, and not four to eight centimètres from it. In order that both the systolic impulse and diastolic shock should be produced in the situation named—in the second left intercostal space, four to eight centimètres from the left border of the sternum—the following three conditions are necessary:—1. displacement of the heart to the left; 2. increased

pressure in the pulmonary artery; 3. an induration of the lung covering the pulmonary artery, or so much retraction of this portion of the lung that the base of the heart is left free; and it is only in induration and contraction of the left lung that the concurrence of these three conditions obtains. In only one case of right-sided disease has Nothnagel observed any similar phenomena.

In speaking of percussion as a means of diagnosis, Nothnagel says that there are two signs which, when present, are certain evidence of contracted lung. These are the displacement of the diaphragm on the affected side upwards, and the dragging over of the mediastinum and the healthy lung towards the diseased side. The auscultatory phenomena and the character of the vocal fremitus present nothing diagnostic, as they vary according to the condition of the contracted lung.

Respecting the etiology of induration and contraction of the whole of one lung. Nothnagel says that much the most frequent cause is pleurisy. The pleurisy is the primary lesion, and it leads to a secondary change in the lung. This change consists mainly in a slow growth of connective tissue (a pulmonary cirrhosis), and it is this growth which leads to the fibroid induration and contraction of the organ. This pulmonary induration is only quite an occasional sequence of pleurisy. Why it should occur in some cases and not in others, it is difficult to explain. Nothnagel thinks that the greater the length of time which elapses before the absorption of the exudation commences to take place, the greater is the liability to this fibroid change. Although pleurisy is the most frequent cause of this condition, it may also result from morbid processes commencing in the lung; but even in such cases the pleura is often simultaneously affected. The morbid conditions of the lung, which may give rise to diffuse induration and contraction, are stated to be—abscess, gangrene, croupous pneumonia, and phthisis.

DISEASES OF CHILDREN.

JACOBI'S RULES FOR FEEDING BABIES.—Dr. Abraham Jacobi (*New York Medical Record*) gives the following rules.

Nursing Babies.—Overfeeding does more harm than anything else. Nurse a baby of a month or two every two or three hours. Nurse a baby of six months and over, five times in twenty-four hours, and no more. When a baby gets thirsty in the meantime, give it a drink of water, or barley-water; no sugar. In hot weather—but in the hottest days only—mix a few drops of whisky with either water or food, the whisky not to exceed a teaspoonful in twenty-four hours.

Feeding Babies.—Boil a teaspoonful of powdered barley (grind it in a coffee-grinder) and a gill of water, with a little salt, for fifteen minutes; strain it, and mix it with half as much boiled milk, and a lump of white sugar. Give it lukewarm, through a nursing bottle. Keep bottle and mouth-piece in a bowl of water when not in use. Give babies of five and six months, half barley-water and half boiled milk, with salt and white sugar; older babies, more milk in proportion. When babies are very costive, use oatmeal instead of barley. Cook and strain. When your breast-milk is half enough, change off between breast-milk and food. In hot summer weather, try the food with a small strip of blue litmus paper. If the blue paper turn red either make a fresh mess or add a small pinch of baking soda to the food. Infants of six months may have beef-tea or beef-soup once a day, by itself, or mixed with other food. Babies of ten or twelve months may have a crust of bread and a piece of raw beef to suck. No child under two years ought to eat at your table. Give no candies, in fact nothing that is not contained in these rules, without a doctor's order.

Summer Complaint.—It comes from over-feeding and hot and foul air; never from teething. Keep doors and windows open; wash your children with cold water at least twice a day, and oftener in the very hot season. When babies vomit and purge, give nothing to eat or drink for four or six hours, but all the fresh air you can. After that time, you give a few drops of whisky in a teaspoonful of ice-water every ten minutes, but not more until the doctor comes. When there is vomiting and purging, give no milk. Give no laudanum, no paregoric, no soothing syrup, no teas.

CROUSE ON ENCEPHALOID DISEASE OF THE LIVER IN AN INFANT.—Dr. J. H. Crouse of Dayton, Indiana, relates the following interesting case in the *Philadelphia Medical and Surgical Reporter* for March 21.

He was called to see the infant daughter of J. P.—, on July 15, 1873, on account of an enlargement in the side. The patient was about five months old, of lymphatic temperament, and healthy general appearance; the sclerotic was slightly jaundiced, the tongue coated, bowels constipated. Upon examination, he found a slight fulness in the hypochondrium; no tenderness; the swelling was rather hard and immovable, presenting an even surface, with no appearance of fluctuation. There was no enlargement of veins, no pain, nor discoloration of surface.

A gentle laxative was given, and compound iodine ointment applied locally. For two months there was scarcely any change. About October 5, the tumour had become about twice as large as when

first seen. An exploring needle was passed in, after which, with a trocar, Dr. Crouse drew off about two ounces of dark bloody albuminous fluid mixed with pus. The tumour could now be felt to be hard and unyielding, and slightly nodulated; after four weeks the countenance presented the expression seen in most cases of malignancy—worn, haggard, and tired. The tumour extended into the epigastric, right lumbar, and umbilical regions, pushing the diaphragm high up, and compressing the right lung. The patient died on January 30.

At the necropsy, thirty hours after death, the growth was found to fill almost the entire abdominal cavity. The tumour was enveloped in a fibrous sheath, and was firmly adherent to the walls of the abdomen and surrounding viscera. Its origin was traced to the right lobe of the liver, which was greatly enlarged and softened. The left lobe was greatly diminished in size. The tumour contained two large cysts, from which were discharged three pints of ichorous bloody and offensive pus. The substance of the tumour was highly vascular; large blood-vessels permeated the entire structure, strong fibrous bands passing through it, giving a grating sound when cut through by the scalpel. The entire mass was estimated to weigh fifteen or twenty pounds. A microscopical examination proved it to be true encephaloid disease. The remaining abdominal viscera presented a healthy appearance. The points of interest, Dr. Crouse shows, are the early age at which the disease appears (he believes it from the family history to have been probably congenital); the absence of pain throughout, and of constitutional symptoms until a late period of the disease; and the large size of the tumour. Both parents were healthy, but the mother had lost two aunts by scirrhus.

RECENT PAPERS.

Nosocomial Septicæmia in Infants. By Dr. E. Hervieux. (*Archives de Toxicologie*, April 1874.)

SURGERY.

OPPIZZI ON LITHOTRITY IN CHILDREN.—Dr. Gerolamo Oppizzi, assistant in the surgical clinic of the University of Pavia, says (*Gazzetta Medica Italiana-Lombardia*, January 24) that the prevalent opinion that lithotritry is less adapted for children than lithotomy, although supported by high authority, is susceptible of exception. In proof of this, he relates two cases which occurred last year in the practice of Professor Porta.

The first patient was a girl, aged five, named Luigia de Gorli, who was admitted on April 5, with stone in the bladder. On the 8th, the child having been anæsthetised by chloroform, a small polypus forceps was introduced, and an attempt was made to crush the stone (which was about three-fifths of an inch in diameter), but in vain; and the instrument was removed without doing any mischief. On the 18th, a small Matthieu's lithotrite was introduced, chloroform having been first given; the instrument moved freely in the bladder, which was not distended with water or urine, but the stone could not be found. On May 6, a small lithoclast, with a flattened beak, was introduced, and the calculus was crushed; the detritus brought away by the instrument showed it to consist of phosphate of lime. In half-an-hour after

the operation, the child sat up in bed, feeling no inconvenience; and there was no subsequent fever. In the course of the day she passed a gramme of small fragments; and some days later she spontaneously voided, without pain, two small angular pieces. Other portions also were probably discharged unnoticed with the urine. At the end of the week after the operation, the symptoms of stone had quite disappeared, and no trace of calculus could be discovered on examination. She was discharged cured on June 19.

The second case was that of a boy, Felice Ramajoli, aged six, who was admitted on July 23. On August 3, chloroform having been given, a small lithotrite was introduced and the stone crushed. The operation last four minutes. Scarcely any febrile reaction followed; and fragments were voided for some days. The operation was repeated on the 10th, and again on the 15th. The bladder was allowed to remain empty on each occasion. On September 6, he was discharged, the symptoms having disappeared, and no trace of calculus remaining. Dr. Oppizzi has since seen him several times, and has ascertained that there is no return of the disease.

In commenting on these cases, Dr. Oppizzi says that these two cases of lithotripsy in children are without doubt exceptional in the ease with which the operation was performed, its rapid success, and the absence of any subsequent complications. Such a fortunate result is certainly not always to be expected; but for small and brittle calculi, lithotripsy is to be preferred, as being attended with less danger to life than lithotomy. A. HENRY, M.D.

LEIRSINK ON A CASE OF FALSE ANEURISM OF THE ANTERIOR TIBIAL ARTERY: APPLICATION OF ESMARCH'S APPARATUS.—Dr. Leirsink relates in the *Deutsche Zeitschrift für Chirurgie* for December, 1873, a case in which a false aneurism was produced by wound of the anterior tibial artery. While Dr. Leirsink was making the diagnosis, and had his stethoscope applied to the part, the aneurism burst. Esmarch's apparatus was immediately applied: the aneurism was laid open, the clots turned out, and the vessel ligatured. The patient's recovery was complete. A. HENRY, M.D.

BOTTINI ON REMOVAL OF A LARGE FIBROSARCOMA OF THE NECK.—Professor Bottini communicated to the Royal Academy of Medicine in Turin on December 19th (*Giornale dell' Accademia*, January 20), the details of the following case.

Maddalena Comoli, aged twenty-seven, a woman of delicate frame, but good health, perceived in February, 1872, a small subcutaneous nodule, of the size of an almond, on the left side of the neck, in the space between the trapezius and sterno-mastoid muscles. The tumour increased in size, and she was treated by several medical men without success; she also applied poultices and various empirical remedies.

On her admission to the hospital at Novara on October 14, 1873, the left side of the neck was occupied by a tumour of the size of an adult head. The posterior part presented a large circular ulcerated surface, with a rather fetid ichorous discharge, and having at several points masses of fungous granulations. The skin covering the tumour was very tense, of a violet colour near the edge of the ulcer, and marked by arborescent veins. The subclavian artery appeared to be in close contact with the tumour; on gently pressing the vessel backward, the pulse in the

corresponding radial artery was immediately stopped. The impulse of the carotid artery was scarcely perceptible, this vessel being pushed against the vertebral column by a projecting portion of the tumour. The patient could scarcely move her head; she suffered from orthopnoea, and, although the tumour was quite painless, she had several times severe pain running down to the scapula and chest.

On October 18, the tumour was removed in the following manner, local anæsthesia being used. Dr. Bottini made a slightly curved incision through the integuments over the occipital fossa, along the spine, as far as the middle of the left scapula. The fibres of the trapezius having been divided, the tumour was found to be enclosed in the deep fascia, to which it was firmly adherent, especially towards the ligamentum nuchæ. The strong adhesions of the tumour to the spinous processes of the lower cervical and upper dorsal vertebrae having been broken through, Dr. Bottini proceeded to remove it from its base, which was entangled among the bundles of the splenius and levator anguli scapulae. Another incision was made from the occipital fossa to the middle of the scapula, and the flap thus formed was turned back as far as the clavicle; and, the tumour being held up by an assistant, Dr. Bottini succeeded in removing it by means of his fingers, aided by a few careful strokes with scissors. More veins than arteries required ligature. The loss of blood was very small. At the bottom of the wound, the carotid and subclavian arteries were seen pulsating in their proper situations; the internal jugular vein was exposed. The wound was united above and below by the twisted suture; the middle part, where the integument was deficient in consequence of the ulceration, was dressed with carbolised glycerine. The patient made a good recovery. A. HENRY, M.D.

OBSTETRICS AND GYNÆCOLOGY.

BOUCHUT ON THE DEATH OF AN INFANT FROM USING AN ACETATE OF LEAD LOTION TO THE NIPPLES.—M. Bouchut (*Gazette des Hôpitaux*, 1873) mentions a case where a lady had used a lotion called 'Eau de Mad. Delacour,' a favourite quack remedy in Paris for sore nipples. She had omitted to wash the lotion off before putting the child to the breast. It was seized with violent colic, and died in a few days with all the usual symptoms of lead-poisoning.

W. C. GRIGG, M.D.

WALLIS ON AN ADDITIONAL METHOD FOR REMOVING FIBROIDS OF THE UTERUS.—P. Wallis (*Dorpat Medizinische Zeitschrift*, vol. iv. 1873) states that in two cases where he failed to remove the growths by the usual methods, he succeeded admirably by means of his hand, tearing through the attachments. Both cases did exceedingly well. The tumour in the one case was about the size of a man's fist; in the other a small soft fibroid.

W. C. GRIGG, M.D.

HECHT ON PLACENTA PRÆVIA, COUPLED WITH FIBROID OF THE UTERUS.—Dr. Hecht (*Allgemeine Wiener Med. Zeitung*, 1873, no. 46) believes this to be the first published case. The patient was a primipara. Up to the eighth month of pregnancy she had been very well, when suddenly she began to lose blood; the hæmorrhage continued for eight days, becoming every day worse. On examination *per vaginam*, there was found in the posterior *cul-de-sac*

at the brim of the pelvis an immovable half globular solid tumour, filling up two-thirds of the inlet, and projecting downwards and backwards into the hollow of the sacrum. *Per rectum*, the relations of the tumour were readily made out. It grew from the posterior wall of the cervix and uterus, impinging on the canal. The child was alive; the head was high up, the os slightly dilated over it, and between the finger and the head was the soft placental mass. The hand, on account of the tumour, was with difficulty introduced and the child was turned, and after much trouble extracted. After delivery, the fibroid could be easily defined as growing from the lower portion of the cervix. The woman died within nine hours, from the effects of the great loss of blood. No *post mortem* examination was allowed.

W. C. GRIGG, M.D.

PUBLIC HEALTH.

WANKLYN ON THE ANALYSIS OF MILK.—In reply to Professor Voelcker's paper, of which we recently gave an account, Mr. J. A. Wanklyn writes: 'In it I read some amusing, but not very wise, comments upon a little "Manual of Milk Analysis," which I have recently published. The Doctor says one might as well talk of a "normal potato," or a "normal cabbage," or a "normal pig," as of normal milk.

'Doubtless this is very funny, but it is neither happy nor true. Potatoes vary greatly in size and weight; some are ten times as big or as heavy as others, but even among the Doctor's own analyses we look in vain for examples of the percentage of milk solids having doubled. After having indulged in such comparisons, it was hardly to be expected that the Doctor should say precisely what it is that I maintain is so very constant in milk. I maintain that the percentage of "solids not fat" is a very constant quantity; and, notwithstanding the generally unsatisfactory nature of his analyses, Dr. Voelcker's results do not entirely conceal this constancy.

'Those who are familiar with the subject will know that no such irregularities as Dr. Voelcker mentions in his paper were observed in Sweden, and that there is the most cogent evidence in favour of there being certain regularities in the composition of milk.

'It is obvious also that irregularities of composition would be simulated by defective analyses. The drying up of milk solids was, until recently, a most tedious and uncertain operation; but, with the modifications introduced by myself, it has now become one of the easiest and most accurate operations which the chemist has to perform.

'I have very little doubt that the extraordinary irregularities described by Dr. Voelcker depend upon defective analysis, and not upon real differences in the samples.

'In Dr. Voelcker's paper he gives a tabular statement of his Cirencester results. From this we gather that the evening milk in October contained 3.76 per cent. of milk-sugar; and that in November the evening milk contained 5.68 per cent. of milk-sugar. Equally curious was the percentage of ash in this wonderful milk, viz., 0.58 in October and 1.15 per cent. in November.

'For my part, I cannot accept these results as true, and regard them as merely affording evidence of the badness of the analyses.'

MACADAM ON THE QUALITY OF MILK SUPPLIED TO TOWNS.—Dr. Stephenson Macadam, in a paper recently read before the North British Branch of the Pharmaceutical Society (*Pharmaceutical Journal*, April 11), says that the recent prosecutions in Edinburgh and other cities and towns, in reference to the adulteration of milk, have proved that there is great necessity for more full information regarding the chemical composition of genuine or normal milk. Having been professionally engaged in some of the cases of alleged adulteration, and having acquired a mass of results regarding the analyses of milk, he has thought it right to give publicity to these researches.

In carrying on the analysis of milk, he says, the special points which may be determined are—

- (1) Specific gravity of the milk.
- (2) Percentage of cream by volume.
- (3) " " solids by weight.
- (4) " " solids not fat "
- (5) " " fat or butter "
- (6) " " ash in solids "

Where it is possible, all these points should be determined. Some chemists attempt to despise the specific gravity and cream tests, and stand by the solids and fat only; whilst others hold, and correctly so, that the specific gravity and cream determinations are excellent guides when they are properly carried out. Necessarily, when all the points are determined—the specific gravity as well as the solids, and the cream as well as the fat—both parties must be satisfied, as the one affords a check to the other, and double certainty and accuracy of results are obtained.

The *specific gravity* is best taken by the ordinary specific gravity bottle, holding 1,000 grains of water at 60° F. The milk should be agitated previously, so as to mix the fat or cream thoroughly throughout, but care must be taken that the agitation is not so violent as to incorporate air-bells with the milk. The temperature of the milk at the time should be 60° F. if possible, but, if slightly above or below that temperature, then an allowance of two-tenths may be made for every degree above or below, being added to the weight when the temperature is above 60° F., and being abstracted from the weight when the temperature is below 60° F. The hydrometers which are supplied with the ordinary lactometers are seldom correct, and, moreover, there is greater uncertainty in reading off the exact figure on the stem indicative of the specific gravity. I always employ the specific gravity bottle. Taking genuine milk derived direct from the udders of the cows belonging to three large dairies in the neighbourhood of Edinburgh, I find the specific gravity to range from 1028.4 to 1035.7; the average of forty-four trials with different milks being 1032.20 (water=1000.00). The variations in the specific gravity of the milks ranging over 7 degrees, undoubtedly indicate a difference in the composition of the milks and in the quantities of the respective components.

The *cream* is determined in an elongated vessel of uniform width, and graduated at the upper part so as to indicate accurately from 1 to 25 per cent. of the whole capacity. The precautions necessary for the uniform and accurate estimation of the proportion of cream obtainable from milk by this creamometer are (1) that the vessels should be of similar size, so as to admit of the fat-globules rising to the surface with equal facility; (2) that the milk should be taken as fresh from the cow as possible, or

that, in contrasting the relative qualities of samples of milk, they should be taken about the same length of time from the cow; (3) that the milk should be well agitated before being placed in the graduated vessel; (4) that the temperature of the milk should be about 60° F.; (5) that the temperature of the room be kept about 60° F.; and (6) that the respective milks be allowed to remain in the creamometers for the same length of time, say twenty-four hours. Working in this manner, I find that genuine milk throws up a proportion of cream ranging from 5 to 11½ per cent. by volume, whilst the average of forty-four trials gave 7·8 per cent.

The *total solids* in milk may be readily estimated by evaporating a given weight of the milk in platinum vessels heated on a water bath. A convenient and excellent bath may be constructed from a common iron pot, about eight inches wide and four inches deep, covered with a sheet of copper-plate about ten inches square, which can be kept in its place by a band being cut out at each side and bent down to embrace the pot. Four circular openings are cut in the copper cover, which admit of four flat platinum basins, about two inches in diameter, being set in the bath. The square corners of the copper cover form a hot plate when the bath is in working order. The milk to be tested having been agitated, a portion is poured into one of the platinum basins and weighed. The amount should run from 80 to 100 grains. The basin and contents are then placed on the water bath, and the water kept briskly boiling for at least two hours. Probably to ensure the thorough drying of the residue, three hours should be taken in all trials, so as to have uniformity in mode of working and greater accuracy in result. The basin and contents are then re-weighed, and the total solids from the given amount of milk are obtained. A calculation then gives the percentage of total solids by weight, and I find that genuine milk gives from 10·57 to 14·54 per cent., the average of forty-four trials being 12·04. There is thus a difference of 4 per cent. in the amount of solids obtainable from samples of genuine or normal milk.

The *solids not fat* are estimated by taking the total solids contained in the platinum basin, and extracting the fat by ether, at the same time heating gently over a vessel containing hot water. On settling for a minute, the ether may then be decanted off into a small weighed beaker. The ether treatment of the total solids should be repeated other three times, so that the solids are acted upon four times by the ether. On drying up the residue in the platinum basin, and re-weighing, the proportion of solids not fat in the amount of milk employed is obtained, and a calculation will give the percentage. Genuine milk gives from 8·74 to 11·23 per cent. of the solids not fat—the average of forty-four trials being 9·62 per cent.

The *fat* may be determined in two ways, either by the loss in weight of the total solids as compared with the solids not fat, or by the evaporation of the ethereal solution and weighing the fatty residue. I do not find the evaporation method so accurate as the estimation by loss. There is apparently some of the fatty matter which escapes over the side of the vessel even when the evaporation is conducted in glass beakers. The difference in weight between the total solids and the solids not fat gives always a higher result and one which I consider is more accurate. Taking, therefore, the loss in weight due

to the extraction of the fat from the total solids by the ether, I find that genuine milk gives a percentage of fat ranging from 1·56 to 3·32, the average of 44 trials being 2·44.

The *ash in the solids* is estimated by burning off the organic constituents and weighing the residue. In genuine milk the ash ranges from 0·62 to 0·76 per cent., the average being 0·69 per cent.

In carrying on these researches, genuine milk was obtained in every instance direct from the udder of the cow. My assistant, Mr. William Jack, went to three large dairies and personally took the samples. He inspected the pails before the milking was commenced, saw all the cows milked, and sampled every milk himself.

From dairy A there were altogether 16 samples taken from 14 cows, 12 of the samples were from the entire runnings of milk from 12 cows, whilst two of the samples were the first of the runnings, and the remaining two samples were the last of the runnings from the remaining two cows. The first five and the last five of the 16 samples were fully analysed, and the results are given in the following table.

| DAIRY A. No. of Cow. | Specific gravity of milk. | Cream per cent. by vol. | Total solids per cent. by weight. | Solids not fat, per cent. by weight. | Fat per cent. by weight. | Ash in solids per cent. by weight. |
|---------------------------|---------------------------|-------------------------|-----------------------------------|--------------------------------------|--------------------------|------------------------------------|
| 12 first of runnings | 1032·9 | 7 | 11·57 | 9·32 | 2·25 | 0·71 |
| 16 last of runnings | 1031·2 | 10 | 12·32 | 9·30 | 3·02 | 0·68 |
| 2 whole runnings | 1033·4 | 5½ | 11·39 | 9·52 | 1·87 | 0·72 |
| 32 first of runnings | 1034·1 | 5 | 11·25 | 9·28 | 1·97 | 0·69 |
| 36 last of runnings | 1029·4 | 11½ | 13·66 | 9·32 | 4·34 | 0·70 |
| 10 whole runnings | 1030·4 | 6 | 10·57 | 8·74 | 1·83 | 0·67 |
| 11 " " | 1032·7 | 5 | 11·42 | 9·70 | 1·72 | 0·70 |
| 12 " " | 1031 | 6 | 11·51 | 9·55 | 1·96 | 0·69 |
| 13 " " | 1031·1 | 9 | 12·62 | 10·04 | 2·58 | 0·74 |
| 14 " " | 1028·4 | 10 | 11·96 | 9·18 | 2·78 | 0·70 |
| Average of the 10 samples | 1031·46 | 7½ | 11·827 | 9·395 | 2·432 | 0·70 |

From the above table it will be observed, that, taking the whole runnings, the specific gravity of the milk ranged from 1028·4 to 1033·4, the cream from 5 to 10, the total solids from 10·57 to 12·62, the solids not fat from 8·74 to 10·04, the fat from 1·72 to 2·78, and the ash from 0·67 to 0·74; whilst the average of the ten experiments gave specific gravity 1031·46, cream 7½, total solids, 11·827, solids not fat 9·395, fat 2·432, and ash 0·70.

The samples of first runnings were markedly inferior in quality, whilst the samples of last runnings were as markedly superior in quality; in no. 1 cow the proportions of cream being 7 to 10 and fat 2·25 to 3·02, whilst in no. 3 cow the variation in cream was 5 to 11½, and the percentage of fat 1·97 to 4·34. It may be stated that the cows, nos. 1, 2, 10, 11, 12, 13, and 14, were of the 'cross' breed, whilst no. 3 was an 'Ayrshire'; that nos. 1 and 2 had calved in January, no. 3 in November, nos. 10 and 11 in June, no. 12 in December, and nos. 13 and 14 in July; and that the cows were fed three times a day, viz., at 7 a.m. mash of draff, oilcake, and boiled turnips; at 12 noon draff and raw potatoes, and at 7 p.m. mash, raw turnips and hay.

From dairy B there were 22 samples of milk taken, 18 of which were from the whole runnings of 18 cows, whilst two samples were the first runnings, and two samples were the last runnings of milk from other

two cows. All of these samples were fully analysed and the following results were obtained.

| DAIRY B. No. of Cow. | Specific gravity of milk. | Cream per cent. by vol. | Total solids per cent. by weight. | Solids not fat, per cent. by weight. | Fat per cent. by weight. | Ash in solids, per cent. by weight. |
|---------------------------|---------------------------|-------------------------|-----------------------------------|--------------------------------------|--------------------------|-------------------------------------|
| 1st first of runnings | 1033'6 | 5 | 10'47 | 9'15 | 1'32 | 0'67 |
| 1st last of runnings | 1030'5 | 13 | 12'94 | 9'17 | 3'77 | 0'73 |
| 2 whole runnings | 1030'5 | 8 | 12'57 | 9'88 | 2'69 | 0'74 |
| 3 " " | 1033'7 | 7 | 11'75 | 10'19 | 1'56 | 0'71 |
| 4 " " | 1033'7 | 8 | 11'91 | 9'32 | 2'59 | 0'68 |
| 5 " " | 1031'8 | 10 | 12'18 | 9'24 | 2'94 | 0'65 |
| 6th first of runnings | 1033'4 | 10 | 10'57 | 9'03 | 1'54 | 0'62 |
| 6th last of runnings | 1029'0 | 14 | 14'09 | 8'99 | 5'10 | 0'59 |
| 7 whole runnings | 1032'0 | 7 | 12'17 | 9'93 | 2'24 | 0'65 |
| 8 " " | 1032'5 | 7 | 11'97 | 9'70 | 2'27 | 0'67 |
| 9 " " | 1031'7 | 7 | 11'52 | 9'23 | 2'29 | 0'62 |
| 10 " " | 1032'8 | 6 | 11'24 | 9'55 | 1'69 | 0'71 |
| 11 " " | 1032'8 | 7 | 11'84 | 9'73 | 2'11 | 0'72 |
| 12 " " | 1030'6 | 9 | 11'66 | 8'94 | 2'72 | 0'64 |
| 13 " " | 1030'6 | 9 | 11'98 | 9'37 | 2'61 | 0'68 |
| 14 " " | 1033'5 | 8 | 12'33 | 9'95 | 2'38 | 0'72 |
| 15 " " | 1031'1 | 6 | 11'48 | 9'52 | 1'96 | 0'73 |
| 16 " " | 1033'4 | 6 | 11'37 | 9'73 | 1'64 | 0'70 |
| 17 " " | 1032'7 | 6 | 11'29 | 9'54 | 1'75 | 0'75 |
| 18 " " | 1029'6 | 8 | 11'41 | 8'85 | 2'56 | 0'69 |
| 19 " " | 1034'0 | 10 | 13'85 | 10'79 | 3'06 | 0'76 |
| 20 " " | 1031'3 | 11 | 12'48 | 9'16 | 3'32 | 0'68 |
| Average of the 22 samples | 1032'14 | 8 | 11'95 | 9'50 | 2'453 | 0'69 |

Taking the above analyses and leaving out the special experiments on the first and last of the runnings of the two cows, nos. 1 and 6, it will be found that over the whole runnings given by each cow, the specific gravity ranged from 1029'6 to 1034'0, the cream from 6 to 11, the total solids from 11'24 to 13'85, the solids not fat from 8'85 to 10'79, the fat from 1'56 to 3'32, and the ash from 0'62 to 0'76, whilst the average of the whole twenty-two analyses gave specific gravity 1032'14, cream 8'0, total solids 11'95, solids not fat 9'50, fat 2'453, and ash 0'69. The samples of the first runnings were again much inferior in cream and fat to the last runnings; thus in cow no. 1 the difference was in cream 5 to 12, and fat 1'32 to 3'77, whilst in cow no. 6, the variation in cream was 5 to 14, and in fat 1'54 to 5'10. In this dairy the cows nos. 1, 7, 8, 9, 10, 11, and 12 were English, nos. 2, 3, 4, 5, 6, 13, 14, 15, 16, 17, 18, and 20 were Ayrshire, and no. 19 was a cross; and the calving of the cows had taken place in January for nos. 1, 8, and 9; October for nos. 2, 3, 4, 5, and 6; December for nos. 7, 10, 11, 12, and 13; August for nos. 14, 15, and 18; September for nos. 16 and 17; June for no. 19, whose milk was nearly out, and February for no. 20, whose milk was only two weeks old. All the cows were fed three times a day on draff and raw turnips.

From dairy C, twelve samples of milk were taken from twelve different cows, and gave the following analytical results (*see next column*).

The above results show that in Dairy C, the milk also varied much in all the testing qualities. Thus, the specific gravity ranged from 1030'4 to 1035'7, cream from 6 to 11; total solids from 10'92 to 14'54; solids not fat, from 9'16 to 11'23; fat, from 1'74 to 3'31, and ash from 0'62 to 0'73; whilst the average of the whole 12 samples gave specific gravity 1033, cream 8, total solids 12'36, solids not fat, 9'91, fat 2'45, and ash 0'69. In this dairy the cows, nos. 1, 2 and 9 were Ayrshire; nos. 3, 4, 5, 6, 7, 8 and 12 were cross; and nos. 10 and 11 were English; and the food consisted of draff, turnips, and oilcake at

5.30 a.m.; draff and turnips at 12 noon, and draff, turnips, and oilcake at 6 p.m.

| DAIRY C. No. of Cow. | Specific gravity of milk. | Cream per cent. by vol. | Total solids per cent. by weight. | Solids not fat, per cent. by weight. | Fat per cent. by weight. | Ash in solids per cent. by weight. |
|---------------------------|---------------------------|-------------------------|-----------------------------------|--------------------------------------|--------------------------|------------------------------------|
| 1 whole runnings | 1031'5 | 9 | 12'92 | 9'94 | 2'98 | 0'72 |
| 2 " " | 1031'6 | 10 | 12'73 | 9'71 | 3'02 | 0'69 |
| 3 " " | 1032'6 | 9 | 12'94 | 10'15 | 2'79 | 0'73 |
| 4 " " | 1034'8 | 6 | 11'96 | 10'22 | 1'74 | 0'65 |
| 5 " " | 1034'4 | 6 | 11'88 | 10'04 | 1'84 | 0'68 |
| 6 " " | 1031'9 | 6 | 10'92 | 9'16 | 1'76 | 0'62 |
| 7 " " | 1032'9 | 6 | 11'04 | 9'34 | 1'70 | 0'64 |
| 8 " " | 1035'7 | 11 | 14'54 | 11'23 | 3'31 | 0'73 |
| 9 " " | 1030'4 | 8 | 11'93 | 9'37 | 2'56 | 0'69 |
| 10 " " | 1031'8 | 8 | 12'22 | 9'69 | 2'53 | 0'70 |
| 11 " " | 1034'4 | 10 | 13'33 | 10'02 | 3'31 | 0'71 |
| 12 " " | 1034'3 | 6 | 11'93 | 10'07 | 1'86 | 0'69 |
| Average of the 12 samples | 1033'0 | 8 | 12'36 | 9'91 | 2'45 | 0'69 |

The average quality of the milk supplied to Edinburgh by the three dairies may be better observed by placing the averages side by side, and then striking an average of the whole samples derived from the 40 different cows. This average of the whole trials may then be contrasted with the lowest and highest results obtained from the whole samples in specific gravity, cream, total solids, solids not fat, fat and ash. The following table exhibits these points.

| | Specific gravity of milk. | Cream per cent. by vol. | Total solids per cent. by weight. | Solids not fat, per cent. by weight. | Fat per cent. by weight. | Ash in solids per cent. by weight. |
|---|---------------------------|-------------------------|-----------------------------------|--------------------------------------|--------------------------|------------------------------------|
| Dairy A average | 1031'46 | 7½ | 11'827 | 9'395 | 2'432 | 0'70 |
| " B " | 1032'14 | 8 | 11'95 | 9'50 | 2'453 | 0'69 |
| " C " | 1033'00 | 8 | 12'36 | 9'91 | 2'45 | 0'69 |
| Average of three dairies, representing forty cows' milk | 1032'2 | 7'8 | 12'04 | 9'60 | 2'44 | 0'69 |
| In all trials— | | | | | | |
| Lowest | 1028'4 | 5 | 10'57 | 8'74 | 1'56 | 0'62 |
| Highest | 1035'7 | 11½ | 14'54 | 11'23 | 3'32 | 0'76 |

These latter figures show that the specific gravity of milk of undoubted genuine quality may range from 1028'4 to 1035'7, or more than 7 degrees, the cream from 5 to 11½, or more than double; the total solids from 10'57 to 14'54, or 4 per cent.; the solids not fat from 8'74 to 11'23, or 2½ per cent.; the fat from 1'56 to 3'32, or more than double, and the ash from 0'62 to 0'76.

These results prove conclusively that milk taken from different dairies varies in chemical composition, and that milk taken from different cows in the same dairy varies still more in chemical properties, notwithstanding that the cows are housed in the same way, fed at the same time and manner, and milked at the same hours. No doubt the quality of the milk must be influenced not only by the food but by the water in the food, the temperature of the byre, the season of the year, whether summer or winter, as well as probably the breed of cow, age, time of calving, and exact state of health of each cow at the time of milking.

The beneficial effects of improved feeding are apparent in several trials which I have made since the foregoing results were tabulated, on the milk of four of the cows belonging to dairy C. The milk was

taken from the cows during the day when it is generally supposed that the milk is richer; but besides that, the dairyman stated that he had commenced to give his cows more nutritious food. The analytical results of the testing of these latter samples of milk were as follows:—

| No. of Cow. | Specific gravity of milk. | Cream per cent. by vol. | Total solids per cent. by weight. | Solids not fat, per cent. by weight. | Fat per cent. by weight. | Ash in solids per cent. by weight. |
|--------------------------|---------------------------|-------------------------|-----------------------------------|--------------------------------------|--------------------------|------------------------------------|
| 1 whole runnings | 1032'5 | 12 | 14'41 | 10'47 | 3'94 | 0'73 |
| 2 " | 1033'6 | 7½ | 12'64 | 10'41 | 2'23 | 0'71 |
| 3 " | 1033'3 | 10 | 14'21 | 11'05 | 3'16 | 0'75 |
| 4 " | 1030 | 10 | 12'91 | 9'70 | 3'21 | 0'74 |
| Average of the 4 samples | 1032'3 | 10 | 13'54 | 10'41 | 3'13 | 0'73 |

These results show a decided increase in the proportion of the several ingredients in the milk, due apparently to the better feeding of the cows.

(To be continued.)

CORRESPONDENCE.

To the Editor of the LONDON MEDICAL RECORD.

CIRCULATORY NOMENCLATURE.

SIR,—Is there no hope of a reform in the nomenclature of the circulatory system?

At present, the confusion arising from the pulmonary veins and arteries becoming pulmonary arteries and veins entirely destroys the perfect beauty and simplicity of the circulatory system.

If, instead of right lobe and left lobe of the heart, venous lobe and arterial lobe were substituted; for right auricle venous auricle, for right ventricle venous ventricle; and in the left lobe arterial auricle and arterial ventricle for left auricle and left ventricle; and all blood-vessels to and from either maintaining their names respectively, as veins and arteries, there would no longer remain the anomaly of the venous blood being carried through an artery to the lungs, and returning as arterial blood through veins back to the heart.

Surely, the advantage of such a change would counter-balance the evil of the abandonment of the original idea of all vessels leading to the heart being veins, and all leading from the heart, arteries.

J. M. W.

April 1, 1874.

[Our correspondent's suggestion would have much to recommend it, if the nomenclature of the circulatory apparatus had to be made for the first time, or were less thoroughly fixed than it is. But custom, 'Quem penes imperium est, et jus, et norma loquendi,' has so completely established the present nomenclature, that any change can scarcely be hoped for.]

MISCELLANY.

MISSIONARY MORTALITY.—The Rev. John A. Vinton has prepared some interesting statistics of the mortality of missionaries at various foreign stations. In Western Africa, Southern India, Southern China, and the Indian Archipelago, the mortality has been from three to nearly seven times as great as the American Experience Tables indicate, while in the Sandwich Islands and in Southern Africa the aggregate mortality has been less. In the

Sandwich Islands, though lying within the tropics, the mountainous nature of the country enables foreigners to select places of residence where the air is as mild as in the mountains of Tennessee; and in South Africa, the mission stations are on an elevated plateau.

But in all that belt of country commencing with Turkey, and extending eastward and southward through Syria, Persia, India, and Southern China, and especially in the Indian Ocean, the mortality of American missionaries has been excessive. In these countries, fevers and the cholera have caused a large ratio of the deaths, while only a very small number have died by violence.

In all the unhealthy countries, with the singular exception of Persia, the mortality among women is much greater than among men. This may be partly accounted for by the younger age of embarkation and the less previous exposure to hardship. Among the missionaries to Turkey, the mortality among females who embarked under the age of twenty-five has been about two and a half times as great as among those who were older at the time of leaving home. Among the female lives in the Sandwich Islands, we find eleven deaths between the ages of twenty-five and thirty-nine inclusive, while the tabular mortality calls for a fraction over six.

IMBECILE CHILDREN IN THE METROPOLIS.—We learn that, in consequence of a committee of the managers of the metropolitan district having a short time since made a report in favour of the imbecile children of the district being kept separate from the adult imbeciles, and placed in one asylum, it has now been determined to appropriate the asylum at Hampstead for this class of cases—arrangements being made for the reception of 110 male and 120 female children.

THE WARMTH OF CLOTHING.—Dr. Von Pettenkofer, in a careful study of this subject recently published, has pointed out that the permeability of stuffs to air is a condition of their warmth. Of equal surfaces of the following materials, he found that they were permeated by the following relative quantities of air, the most porous, flannel, such as is used ordinarily for clothing, being taken at 100:—Flannel, 100; linen of medium fineness, 58; silk, 40; buckskin, 58; tanned leather, 1; chamois leather, 51. Hence, if the warmth of clothing depend upon the degree in which it keeps out the air from our bodies, then glove-kid must be 100 times warmer than flannel, which everyone knows is not the fact.

The whole question, then, is resolved into that of ventilation. If several layers of the same material be placed together, and the air be allowed to permeate through them, the ventilation through the second layer is not much less than through the first, since the meshes of the two form a system of continuous tubes of uniform diameter, and the rapidity of the movement of the air through these is affected merely by the resulting friction. Through our clothing, then, there passes a stream of air, the amount of which, as in ventilation, depends upon the size of the meshes, upon the difference of temperature between the external and internal atmosphere, and upon the velocity of the surrounding air. Our clothing, then, is required, not to prevent the admission of the air, but to regulate the same so that our nervous system shall be sensible of no movement in the air. Further, our clothes, at the same time, regulate the temperature of the contained air, as it passes through them, so that the temperature of the air between the clothing and the surface of our body averages 84° to 86° Fahr.

The hygroscopic property of different materials used for clothing essentially modifies their functions. This property varies with the different materials; wool, for instance, takes up more water than linen, while the latter takes up and gives off its watery contents more rapidly than the former. The more the air is displaced by water from the clothes, the less will be their power of retaining the heat; in other words, they conduct the heat more readily, and hence we are quickly chilled by wet garments.

M. VILLEMIN has been elected a member of the Academy of Medicine in Paris, in the section of Medical Pathology. He is well known as having been one of the first to make experiments on the inoculability of tubercle.

PRESERVATION OF MEAT.—M. Poggiale described to the Academy of Medicine, at a recent meeting, the process followed by M. Tellier, in his establishment at Auteuil, near Paris, for the preservation of meat. The vessels or chambers in which the meat is enclosed are kept cool by the alternate vaporisation and condensation of methylic ether. Specimens of meat and game that had been kept in this way for weeks were examined, and found to be in good preservation. The game, however, had lost somewhat of its flavour.

THE WRITING OF ATAXIC PATIENTS.—At a recent meeting of the Biological Society of Paris, M. Onimus showed specimens of the handwriting of ataxic patients. They write in the same way as they walk, their writing presenting the characteristic irregularity and jerky abruptness. The letters are not rounded, the a's and o's being nothing but straight lines; whilst others have undefined terminations, such as the q's and the p's. At a more advanced stage, just as the foot strikes the ground with violence, so the pen leans so heavily on the paper as to perforate it. Therefore, ataxic patients only use pencils.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & CO.—Calcutta: THACKER, SPINK & CO.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & CO.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & CO., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, APRIL 22, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

SPIEGELBERG ON EXUDATIONS IN THE NEIGHBOURHOOD OF THE FEMALE GENITAL TRACT.*

Professor Spiegelberg states that further experience has justified his former assertion that these exudations are the most important affections with which one has to deal in diseases of women. A knowledge of this complaint is entirely of modern date, and, thanks to French authors, we are now in a position to take a fair survey of it. Already there exists two opposing doctrines. One maintained especially by Bernutz and Goupil, is that the peritoneum covering the female pelvic viscera and the neighbouring pouches and folds is the more dominant factor, and that the disease is a pelvi-peritonitis; the other is, that the disease has its origin in the cellular tissue in which the genital tract is situated, and which forms the parenchyma of the broad ligament; and that a phlegmon of the pelvic cavity is the chief cause of these exudative swellings and nodules. Authors are not yet unanimous whether perimetritis or parametritis is the more frequent, and in some cases the distinction is exceedingly difficult. It is a wide field of contention amongst writers, and this arising principally from want of clearness in the anatomical representations, and from imperfect knowledge of the relations of the serous membrane to the genital organs and to the pelvic fascia, and of the latter to the uterus and vagina. Dr. Spiegelberg relates much that is already well known, for the purpose of making a few remarks on their connections, &c., which, he considers, will have some influence on the etiology of this disease.

There are two plates: one a modified copy of Kohlrausch's vertical section of the pelvis and its organs; the other a transverse section, showing the vessels on the posterior surface of the uterus and cervix with the rectum and half of the peritoneum removed. He gives a brief anatomical sketch, and by aid of these plates attracts particular attention to the great amount of loose areolar tissue beneath the peritoneum at the point of its reflection from the anterior surface of the uterus (opposite the internal os), and where it covers the bladder. Between the bladder and cervix and upper portion of the vagina, it diminishes considerably. This tissue is exceedingly vascular, and rich in lymphatics. On the posterior surface of the uterus, the serous membrane, instead of descending in a direct line, opposite the middle of the neck, is separated from it by a bulging mass of cellular tissue; thence it is reflected along the hinder part of the vagina, and up the anterior surface of the

rectum, being for a space of one or two centimètres below this mass, in very close contact with the vagina. By this arrangement, a retro-uterine as well as a retro-cervical phlegmon becomes possible.

Laterally, the peritoneum, about the middle of the uterus, suddenly quits it, being reflected over the broad ligaments, whose roof it forms, leaving free a triangular space with its apex pointing upwards, full of loose areolar tissue. Thence the serous membrane spreads upwards over the sides of the pelvis, and over the iliac fossa. Between the peritoneum and the recto-vesical fascia there is a large quantity of cellular tissue and vessels. Beneath the recto-vesical fascia is the ischio-rectal fossa, containing vessels, a large amount of fat, and areolar tissue.

Luschka, from their relations, has named these three cavities, from above downwards, the *cavum pelvis peritoneale*, the *cavum pelvis subperitoneale*, and the *cavum pelvis subcutaneum* (ischio-rectal fossa). Of these cavities, the subperitoneal is the most important, as it contains not only the trunks of vessels, but also venous plexuses, besides abundance of veins and lymphatics, whose roots are embedded in the uterus. It is here that the ante- and retrocervical subperitoneal tissues become united. The cervix is enveloped in cellular tissue, gradually diminishing in quantity from above downwards. This is particularly important:—1. Because this tissue is intimately connected with the parenchyma of the neck, and in a measure forms its capsule; 2. Because it not only conducts blood-vessels and lymphatics to and from the tissue of the cervix, but of itself represents a cavernous structure (Rouget); 3. Because it takes part in all irritations and tumefactions of the cervix. In lesions of the cervix, on account of the thinness of the cervical walls, the cellular tissue easily becomes affected. The slightest lesion may set up inflammatory swellings; and, from its very construction, the tissue is an extremely favourable place for the reception and spread of septic matter by the blood-vessels and lymphatics.

Virchow (*Archiv*, no. xxiii.) introduced the name of parametritis to denote inflammation of the cellular tissue surrounding the lower portion of the uterus and the vaginal substructure. This word has later come to mean inflammation, not only of the parenchyma of the broad ligaments, but also of the entire pelvic fascia (Matthews Duncan), and hence has arisen some confusion.

The pathological importance of the pelvic fascia in the different situations, is very various. Dr. Spiegelberg proposes to give the name 'parametranal' to that layer, copiously supplied with blood-vessels and lymphatics, which surrounds the lower segment of the uterus and the base of the vagina for about two centimètres in width. Its inflammatory infiltration and subsequent induration would be parametritis; but, in order to prevent mistakes, it would be better called 'parametranal inflammation'—preserving the French nomenclature for inflammation of the parenchyma of the broad ligament and the pelvic fascia, viz., 'phlegmon of the broad ligament,' and 'phlegmon of the pelvic fascia.'

From this brief sketch, it is easily seen that intra-peritoneal exudation must very rarely occur in front, hardly ever laterally, but invariably behind in Douglas' pouch, consequently retro-uterine as well as retro-vaginal. As in the commencement all peritoneal exudations are fluid, they flow as a matter of course downwards, collecting at the bottom of Douglas's pouch, which is the most dependent portion of the

* *Sammlung Klinischer Vorträge*, no. 71, 1874.

abdominal serous membrane. They only appear as tumours, when encysted through gluing together of the intestine and pelvic viscera with the parietes by lymph. The process is generally gradual, but in some instances very rapid. Not a few of these cases are diagnosed as retro-uterine hæmatoceles. The contour of the swellings is always smooth and uniformly arched. The tumour is lowest at its centre, sometimes reaching down as far as the external os, especially in women who have borne children, in whom Douglas's pouch extends lower down. Laterally, it never touches the sides of the pelvis, but approaches nearer to them from below upwards. Its border is ovoid. The uterus is pushed forwards and upwards to an extent depending on the size of Douglas's pouch and the amount of fluid effused.

An intraperitoneal exudation has not a retro-uterine position except when it collects in occasional hollows, previously formed by false membranes and adhesions, either between the bladder and uterus, or laterally between it, the Fallopian tubes, and ovaries. Adherent loops of intestines may simulate tumours. The high situation of these tumours, and their being placed permanently laterally and in the posterior part of the *cavum peritoneale*, secures their correct diagnosis; still there are cases in which it is exceedingly difficult to distinguish them from phlegmonous nodules.

Professor Spiegelberg lays great stress on the fact that 'parametranal phlegmon forms a tumour from its very first commencement,' from being surrounded by a layer of cellular tissue. Its consistency varies; at first it is boggy, then fluctuating; later on, fixed, hard, knotty, and cord-like. The swelling may be on any side of the cervix; it is rarely large in front, from the small amount of areolar tissue between the bladder and neck, but may extend upwards along the abdominal walls for some distance, presenting a board-like structure, with a sharp well-defined border closely attached to the abdominal integuments, reaching to various heights in the inguinal region, and losing itself in the iliac fossa. It may be situated posteriorly, forming a retro-cervical parametritis, and is frequently mistaken for an intraperitoneal exudation, with which it has a great tendency to combine; it is distinguished by its diffuse border gradually emerging into the *parenchyma* of the broad ligament, and its marked retro-vaginal position, pushing the cervix forwards and upwards. As a rule, parametranal exudations are situated laterally. If they be of large size they extend into the broad ligament, so that a phlegmon of the latter may be a continuation of a parametranal inflammation. Still, phlegmon of the broad ligament may be primary, and of various sizes and positions, implicating perhaps the whole of the pelvic cellular tissue. These nodular exudations project downwards, shortening the contiguous portion of the vagina, and can be only felt through the abdominal walls when very large. Their contour is irregular, lumpy, gradually passing into healthy tissue and, as a rule, fixing the uterus to the pelvis.

As previously stated, Dr. Spiegelberg considers the pathological importance of the parametranal tissue the greater; and in studying the etiology of the affection, the truth of this assertion is very apparent. Any injury to the lower segment of the uterus and upper portion of the vagina, however brought about, may set up inflammation of the tissue. It is no accidental coincidence, as no gynecological affection is so frequent, not only as the result of child-bed,

but also from any lesion. The limits of the disease are entirely dependent upon the idiosyncrasy of the patients, and beyond the control of art. Septic parametranal phlegmon, and even septicæmia have followed the most trivial wounds. Its spontaneous origin from so called internal causes cannot, Spiegelberg thinks, be denied. Primary phlegmon of the broad ligaments chiefly originates spontaneously, proceeding from tumefaction of the membrane surrounding the situs of the ovary through some irritation of that organ, or from some small menstrual hæmorrhage into the broad ligament. Now and then they take their origin for external injuries.

He believes that pelvic peritonitis originates occasionally as a sequence of paracervical inflammation; from contusions and lacerations of old standing, false membrane, the results of a previous confinement; but generally from an endometritis and salpingitis, or from some menstrual disturbance. In the former it is principally the result of a gonorrhœal inflammation, in the latter it comes through the retention of some small clots in the above organs, causing extravasations into the peritoneal cavity, and on the surfaces of the Fallopian tubes and ovaries.

He sums up by saying: 'Parametranal nodules proceed from some pathological condition of the lower section of the internal genital organs.' Phlegmon of the broad ligaments follows parametranal phlegmon, or springs from the parovarian membrane. Pelvipеритонitic exudations accompany affections of the uterus and the Fallopian tubes, particularly of its internal surface; the latter are less frequent than the former and are most generally secondary; they never progress so insiduously as inflammations of the cellular tissue tend to do. Only at an early date, by careful examination, can the course of the development of the disease be learned. Frequently enough, this knowledge is concealed. The history of parametranal and periuterine inflammation will long be a fertile field of clinical, as well as of anatomical and gynecological observation.'

W. C. GRIGG, M.D.

CHARCOT AND OTHERS ON AUDITORY VERTIGO (MÉNIÈRE'S DISEASE).

Several important articles have recently appeared on what is variously called 'auditory vertigo,' 'vertigo ab aure læsâ,' or from its discoverer, Ménière's disease; the most recent and one of the most able is by Charcot. This physician's great knowledge of nervous diseases and remarkable power of original research, enable him to give any such subject wide and yet precise bearings. Charcot remarks that, in spite of recent papers on the subject (Knapp and Duplay), the disease is not so generally known as it should be. He shows that the symptoms of Ménière's disease are important not only for the aural surgeon, but for all practising medical men. For those specially interested in nervous disease, a thorough knowledge of them and of their relations to other symptoms of disease of the nervous system is essential. We give reference to Charcot's paper and to some others in the subjoined footnote.*

* *Le Progrès Médical*, Jan. 24 and 31, 1874, 'De la Maladie de Ménière.' Knapp's paper (to be especially referred to in the above article), 'A Clinical Analysis of the Inflammatory Affections of the Inner Ear,' and a paper by Gustav Brunner, of Zürich, 'On Vertigo occurring in Affections of the Ear (Auditory Vertigo),' are to be found in the

If a patient have an attack of giddiness, with vomiting, especially if his vomit contain bile, it frequently happens that a superficial view is taken of his case, and that an associated aural trouble is carelessly overlooked or disregarded. Charcot says that auditory vertigo may be erroneously put down to apoplectic cerebral congestion, to *petit mal*, but that it is most often attributed to gastric disorder. Indeed, Trousseau says that vertigo 'ab aure læsâ' greatly resembles vertigo 'a stomacho læso.' In this country auditory vertigo is very often, we believe, ascribed to affection of the liver; there being, however, no very good reason for this diagnosis, mostly, indeed, only the inconclusive evidence in favour of it that bile is brought up; but so it is in all urgent vomitings, however caused. Whatever view we may take of the cause of a paroxysmal vertigo, nothing justifies us in neglecting investigations for aural trouble or in ignoring them when found. It would be as absurd to ignore the hemiopia and other visual troubles preceding the headache and vomiting of *migraine*. This disease, often passing under the unfortunate name of 'sick-headache,' by the way, is now, thanks in this country especially to Anstie, Latham, and Living, shown to be really a nervous affection, and not a mere stomach-and-liver affair, and thus not one requiring remedies exclusively addressed to gastric and hepatic derangement.

The case which Charcot relates is a very important and a very remarkable example of Ménière's disease. But before we speak of it, we may give a brief account of some of the symptoms of that affection.

The patient has, usually, a sudden attack of giddiness, accompanied by reeling gait, great pallor of the face, free perspiration, feeling of fainting, or even actual loss of consciousness; he feels sick or actually vomits. At the same time, there is usually a great noise in one or in both ears; it may be that the patient's hearing has been good before, and that he is afterwards deaf, or it may be that there has for long been some kind of aural trouble. We speak only of the prominent symptoms, of the giddiness, the reeling, and the affection of hearing. The symptom vomiting, being obtrusive, cannot be disregarded nor underrated, and therefore need not be commented on; there may, however, be only nausea.

The important matter is to show how the aural trouble is associated with the vertigo and reeling. We use the very general expression 'aural trouble' because, as we shall see, the kind of affection of the ear varies very much, although possibly in the production of auditory vertigo the immediate cause is some affection of the labyrinth.

For our purpose, the labyrinth may be taken to consist of two functional parts, the cochlea and the three semicircular canals; these two parts have corresponding divisions of the auditory nerve. It seems to be agreed that the cochlear division is for the perception of musical sounds. As

to the function of the three semicircular canals, or, speaking strictly, of their contents, there is a difference of opinion. Helmholtz's view is that they serve in the appreciation of ordinary sounds. The view taken by Goltz is that, 'being subservient to the maintenance of poise, they are, as it were, the organ of the sense of equilibrium of the head, and thereby of the whole body.' (Knapp, op. cit., p. 224.) There are certainly facts supplied by experiments on animals, the well-known experiments of Flourens, which show that the canals have something to do with the regulation of movements, chiefly those of the head. The following quotation from Vulpian's *Physiology of the Nervous System* tells us not only that injury of them produces disorderly movement, but that each canal—judging from the fact that a particular disorderly movement follows lesion of each—has some special duty, serves to regulate some particular group of movements of the head, and thus indirectly to regulate some group of movements of the whole body in locomotion.

'Two of the semicircular canals are vertical, the third is horizontal. In this pigeon, the canals of which have been carefully exposed, I break the horizontal canal on one side, then that of the other side. The animal gives obvious signs of pain, and his head moves violently from right to left and from left to right, following a horizontal line; at the same time the eyeballs are agitated, and you can observe further that the animal turns itself round upon its vertical axis. In this other pigeon, I cut the inferior vertical canal on each side, and I determine movements of the head from above downwards as impetuous as the preceding ones; then the animal throws its head backwards; it shows, as you see, a tendency to fall backwards. I cut now the upper vertical canal on each side on this third pigeon. The vertical movements of the head immediately come on; they are very violent and analogous to the preceding ones. Nevertheless you see that the animal tends to fall forwards, and that to stop these movements, it ends by leaning the top of its head forwards on the ground.'

It is right to mention that Dr. Brown-Séquard has said, 'I have ascertained that the phenomena observed in experiments on these canals, do not depend on the section of these canals, as this operation may not cause these phenomena, but that they are the results of irritation of the auditory nerve, from the dragging on it by the membranous semicircular canals at the time when we divide them.'

We must bear in mind the differing positions of the canals in order to understand Goltz's hypothesis. Goltz thinks that the terminations of the nerves in the canals are in health excitable by pressure or tension, as the tactile nerves of the skin are. The excitation is by the pressure of fluid, which pressure, according to him, varies, for physical reasons, with the position of the head. The central nervous system, at any given time, receives information as to the position of the head from the nervous contents of that canal, which being then most dependent is consequently most excited by pressure. If such be the physiology of the canals, the interpretation of the results of damage of them follows easily. When one or more of these canals is damaged, the central nervous system is wrongly informed as to the position of the head. We may suppose that this results either because in sudden lesion an exaggerated impression is transmitted to the brain from the over-excited canal, or because as a consequence of very

Archives of Ophthalmology and Otology, vol. ii. no. 1. In the *Archives Générales de Médecine*, June 1, 1872, appears a review of these papers by Dr. Simon Duplay, who gives a very clear and succinct account of Ménière's disease. A brief account of Ménière's disease is given by Dr. Ramskill in his article 'Vertigo' in *Reynold's System of Medicine*, vol. ii. It is described by Trousseau in his lecture, 'Vertigo a Stomacho læso' (New Sydenham Society's *Translations*, vol. iii. p. 549.) In the *Guy's Hospital Reports* for 1873-4, there are papers on the subject by Dr. Wilks and by Mr. Hinton. The Reporter has given an account of the affection (chiefly compiled from Knapp and Trötsch) in the *Medical Times and Gazette*, Aug. 17, 1872.

extensive injury of a canal its nervous contents cannot be excited at all, and thus there is no impression for transmission. In consequence of the centre over-acting on wrong information, or underacting because it is without information, certain factors in the locomotor movements will be out of harmony with the rest. Thus there will be reeling. There is, however, in slight cases, not reeling, but simply vertigo. However, the reasoning is the same; vertigo (as is plainly seen in the study of cases of palsy of ocular muscles) is a motor symptom; it is, the Reporter believes, a rudimentary or incipient disorder of co-ordination of locomotive movements; it is frequently, however, spoken of as a cause of reeling. The disturbances of equilibrium are, Goltz thinks, temporary, when the semicircular canals are injured but not one side. Goltz's hypothesis at first glance appears to refer only to movements of the head. He shows, however, that the movements of the body are dependent on, perhaps we may say 'led by,' those of the head. This view seems to us to be supported by the effect of section of the muscles of the back of the neck in dogs (in the operation to expose the occipito-atloid space); the result is, Magendie and Bernard state, disorderly movement like that of drunkenness. Bernard* finds, too, that although section of the muscles of the back of the neck of pigeons does not produce disorderly walking, it destroys their chief mode of locomotion; they cannot fly.

These last-mentioned facts have a still wider bearing. The auditory nerve, as Lockhart Clarke has long since pointed out, sends a large division to the cerebellum. According to Meynert, the whole of it is lost in the cerebellum. It is a fair speculation, then, that the nervous centres of which we have metaphorically spoken as being wrongly informed, in cases of lesions in the semicircular canals, lie in the cerebellum, or, in other words, that the divisions of the auditory nerves in the canals are afferent to centres in the cerebellum for certain movements of the head, for those which take the lead in and regulate locomotion. This would accord with the generally accepted view that the cerebellum is the organ for the co-ordination of movements of locomotion; it matters not whether the cerebellum be disturbed from actual disease in it, or be disturbed by irritation propagated to it from without. The word co-ordination is, however, not a safe one to use, for there are still some who speak of a 'faculty of co-ordination,' and even of a centre for it. The reporter believes that the cerebellum is only to be considered the organ of co-ordination of movements of locomotion, in that it represents more especially the locomotive movements of the spine (head and trunk). The disorder of co-ordination of movements of locomotion, actual as in reeling, or rudimentary as in vertigo, from disease of this centre, is owing, he considers, to paresis of the spinal muscles. Hence the significance of the effect of section of the muscles of the back of the neck, in effect a paralysis of them, in the above-mentioned experiments of Magendie and Bernard. The seemingly erratic action of the legs in some cases of cerebellar disease, is for the preservation of balance consequent on the spinal paresis; the patients keep their legs widely apart, and, so to speak, their legs run after the trunk to 'under-pin' it in its various over-inclinings from side to side and from back to front.

The disorderly walk which occurs early in some cases of disease of the cerebellum is a reel; it is a walk like that of a drunken man; so also is, so far as one can judge by reports of patients and observation of a few cases, the walking of patients during the paroxysms of Ménière's disease. The speculation is that the last link in the morbid chain in Ménière's disease is disorder of the centres in the cerebellum, which especially empower the muscles of the neck and trunk. [The only statement of the hypothesis, that the vertigo and reeling in cases of cerebellar disease depend on paresis of the spinal muscles, which I can find, is contained in Niemeyer, who quotes Immerman (*Humphreys and Hackley's Trans.* vol. ii. p. 188 and p. 244). At first glance it seems an inadequate explanation of the disorderly co-ordination of reeling. But we must take note of secondary effects of paralysis; these are best seen in cases of palsy of oculo-motor nerves. There no doubt are, in cases of spinal paresis, indirect results of this paresis analogous to the 'erroneous projection' and 'secondary deviation' in cases of paralysis of the ocular nerves.—*Rep.*]

So far we have said nothing of the associated deafness. This, as Knapp urges, shows that the lesion in cases of Ménière's disease is not limited to the semicircular canals. He brings forward special evidence on this matter. He points out that not only is there partial deafness, but that there is deafness for certain musical tones, which, borrowing the form of an expression of ophthalmologists, he describes as 'a contraction or limitation of the field of audition.' This is, he thinks, clear evidence that the cochlea itself is involved also. Besides the positive value of this conclusion, it is negatively valuable as showing, to use Knapp's words, that Ménière's disease 'is neither an affection of the trunks of the auditory nerves, nor of their centre in the brain.' (Op. cit. p. 277.)

FORENSIC OPHTHALMOLOGY.

ON INJURIES OF THE EYE IN THEIR MEDICO-LEGAL RELATIONS. BY PROFESSOR ARLT, OF VIENNA.*

(Continued from page 226.)

4. *Bursting of the Globe.*—Whether bursting of the cornea can occur as a result of sudden compression, is doubtful. In the few cases where this is alleged to have been observed, the suspicion is not excluded, that the cornea was struck by a more or less sharp corner or edge of an instrument.

Cases of bursting of the sclerotic are but rare. The rent extends, without exception, through the ciliary process. Of bursting of the posterior part of the sclerotic, first, indeed, detected after enucleation of the eye, one case only has been recorded by Bowman (White Cooper, *On Wounds and Injuries of the Eye*, 1859).

Diagnosis.—The sclerotic rent is linear or somewhat curved, more or less indented, from nearly a quarter of an inch to half an inch long. It generally rises parallel with the edge of the cornea, at a distance of about $\frac{3}{40}$ to $\frac{1}{5}$ of an inch from the free edge. In one case only (Schröter, *Klinische*

* *Leçons sur la Physiologie et la Pathologie du Système Nerveux*, vol. i. p. 497.

* *Wiener Medizinische Wochenschrift*, March 28 and April 4.

Monatsblatt, 1866) the rent formed a flap. (A man fell on an anvil, a corner of which struck him near the inner angle of the left eye. There was first found a rent in the sclerotic, passing horizontally outwards several lines from the outer edge of the cornea. Four days later, the chemosis of the cornea having diminished, a second rent was seen extending upwards and inwards from the outer end of the first, so as to form an acute-angled flap; and five days afterwards a third rent was found, extending a few lines inwards from the inner or upper edge of the cornea. The reduction of the inflammation was followed by a shrinking of the cornea; the lens was also dislocated, probably at the time of the fall.) If the rent run near the cornea, the conjunctiva is generally torn, and then the lens may entirely, or in great part, escape, or a portion of the iris, of the lens-capsule, or of the vitreous body may hang out of the wound.

If the conjunctiva remain sound, a sac is formed, in which blood, the fluid of the aqueous chamber, iris, lens, and vitreous body may be found; and these contents may more or less conceal the rent. The weakness of the globe, which may even remain after the union of the wound, the drawing forwards of a portion of iris towards the part suspected of being the seat of injury, and perhaps the evidence of changes in the lens, if the chamber be not full of blood, may lead to a diagnosis, if any doubt remain after careful inspection of the cornea, or if there be general chemosis. The presence of the lens under the conjunctiva is shown, independently of its size and shape, after the absorption of the blood, by the complete reflection of light at the edge of the capsule, after cataractous opacity has commenced in the lens. In time, the lens may in some cases be absorbed, leaving only some fatty and saline *débris*.

These ruptures always indicate that a blunt instrument has been applied with great force and rapidity. There appears to be no indication of any special predisposition; the injuries are almost confined to adults, and are most frequent in the second half of life.

Prognosis.—According to the hitherto recorded observations, it appears as if the force of the blow is spent in the laceration of the ciliary process and the sclerotic; the retina and choroid (behind the ora serrata) are but little if at all affected. The circumstance that these ruptures mostly occur inwards, or upwards and inwards, rarely upwards and outwards, and very rarely downwards, indicates that the eye has been struck in its anterior circumference, but far from the cornea.

The traumatic reaction after the injury does not readily reach a high degree. The danger lies principally in extensive injury of the vitreous body, which may lead to subchoroid hæmorrhage, and in subsequent irritation of the iris, either through its becoming pinched in the cicatrix, or through the pressure of the lens on the iris and ciliary processes. If much of the vitreous body escape into the wound, either violent reaction on account of the considerable collapse of the globe, or severe choroidal hæmorrhage, is to be apprehended: or there is danger of the occurrence of separation of the retina gradually manifesting itself after weeks or months.

The filling of the anterior chamber with blood is a matter of much less importance. Numerous cases are recorded, where, after total escape of the lens, persons have been able to see, with the aid of cataract-glasses, as well as those who have been operated on

for cataract, and have remained for years in this condition.

Treatment.—The first indication is to prevent further discharge of the contents of the globe. During the first days the patient should lie on his back, cold should be applied, and both eyes kept closed; and he should as far as possible avoid every action tending to retard the flow of blood through the descending vena cava (such as coughing, straining at stool, &c.). If a large portion of vitreous body and of iris hang out of the wound, a part may be cut off in moderately quiet individuals; but this is not absolutely necessary. The exposed mass of vitreous body in a few days becomes opaque, constricted at the base, and is at last thrown off; the iris is fixed in the opening, and is gradually bridged over by exudation and conjunctiva, and levelled down. If this do not occur, it may be cut away. If the lens press on the iris or on the ciliary processes, an endeavour should be made to remove it.

If the conjunctiva be not torn, but only protruded in the form of a sac, the opening and emptying of the sac should be delayed until it appears (from the state of tension of the globe) that the rent in the sclerotic and uvea is closed. If panophthalmitis (filling of the interior of the blood with pus, and its protrusion) appear, the case can scarcely be prevented from going on to wasting of the bulb, though a compressive bandage may be of use. The severe pains can only be allayed and cut short, at first by the use of ice-cold applications, afterwards of lukewarm, with the aid of opiates or chloral-hydrate. At last, when the discharge of pus through the sclerotic is long delayed, a puncture at one or more of the most prominent points may be the only means of relieving the patient.

The worst cases are those in which, from dragging or strangulation of the iris, or its irritation by the pressure of the dislocated or swollen lens (with its capsule), or from a later effusion of blood into the vitreous space, a slow inflammation (with increase of pressure) is set up and continued in the uveal tract; in such cases, there is danger of sympathetic iridocyclitis of the second eye.

5. *Laceration of the Uveal Tract* (iris and choroid) is generally indicated by an effusion of blood into the aqueous chamber or into the vitreous body (*hæmophthalmus*).

Effusion of blood into the anterior chamber, in an eye that has not previously been inflamed (except in cases of scurvy and of intraocular tumours) always indicates concussion of the eye or a penetrating wound. Its source is generally the iris, rarely the ciliary processes or the posterior half of the eye. The blood may entirely fill the anterior chamber, or may be present in such small quantity (in the fold between the iris and the corneo-scleral border) that it can only be found after careful search. It generally lies below; but may be met with above or to the side, or between the fibres of the iris at the points where laceration has taken place. It can then be generally discovered only by concentrated light. In eyes previously healthy, especially in early age, the blood which has filled the whole chamber may be entirely absorbed in thirty-six hours. Some colouring matter, however, generally remains for a time, undergoing changes of colour, and appearing as a yellow or pale red covering, through which the iris, when not inflamed, can be distinctly seen.

6. *Effusion of the Blood into the Vitreous Body* after concussion with bursting of the choroid (or

after penetrating wounds not reaching the lens) produces, according to its amount and situation, disturbance of vision in different degrees, up to the point of being only able to distinguish between complete darkness and strong light. Large masses of blood in the vitreous body can of themselves absorb all light, and sometimes they even totally destroy the quantitative sensibility to light.

When ophthalmoscopic examination is prevented by effusion of blood into the anterior chamber, or by opacity of the lens, the means that has been employed since Von Gräfe to determine the functional capability of the retina in cataract, may be used for ascertaining whether we have to deal only with an abundant effusion of blood in the vitreous body, or also with elevation of the retina (by blood or serum between it and the choroid) or with laceration or concussion of the structure (commotio retinæ). 'If,' says Von Gräfe (*Archiv für Ophthalmologie*, vol. iii.), 'when the patient is examined with the lamp in a dark room, there exist a perfectly distinct perception of light, about as much as in mature cataract, and if this be nearly equally distinct in all directions, there may be an abundant circumscribed hæmorrhage in the vitreous body, but there is certainly no separation of the retina. If the quantitative faculty of vision be moderately impaired, and the appearance of light in the lower part of the field of vision somewhat more distinct than above, it must not even then be concluded that there is separation of the retina; a large amount of hæmorrhage in the vitreous body with sinking of the coagula may produce the impairment and inequality. If in such cases it be desired at an early period to determine whether there is reason to suspect separation of the retina, the patient is made to repeatedly move the eye rapidly upwards, so as to disturb the coagula in the vitreous body; and then we note whether the inequality in the perception of light is changed in any way. The patient may also be made to lie on one side for some time; and it may then be observed whether there is a corresponding change in the indistinct perception of light. If there be an enormous difference between the perception of light at the upper and lower parts, and especially if the perception be very remarkably diminished, a separation of the retina may be diagnosed. . . . Moreover, it must not be forgotten that separation of the retina may occur or increase at a later period, when the opacity of the vitreous body is diminishing. I will not deny that limited separation of the retina in hæmophthalmus may be overlooked in spite of the most careful examination of the perception of light (in consequence of the dispersion of light); and in many cases where there is at the same time extensive hæmorrhage in the vitreous body it may remain unknown; but a great advance in diagnosis and prognosis has been made by the examination of perception of light and homocentric illumination.

Prognosis.—Small quantities of extravasated blood in the vitreous body of themselves produce more or less marked impairment of the acuteness of vision. The patient complains of a dark cloud or flocculi floating before his eyes; and often (at first) white objects appear red.

Absorption takes place much more slowly than in the chambers; it may require five or six weeks. Movable *scotomata* very often remain for a long time, or even permanently. Whether a destructive defect of the field of vision (or fixed scotoma) or more or less limitation of the field of vision will remain,

depends partly on the situation and extent of the rupture of the choroid, partly on the immediate or subsequent changes in the retina (see sections 8 and 9).

As long as the blood collected in the chambers or in the vitreous body prevents sufficient examination of the eyes, the prognosis should be reserved, especially when the violence applied was great, or if the eye were previously not perfectly sound—*e.g.* if it were very myopic. The quantitative sensibility to light may be removed for two or three weeks by blood collected in the vitreous body, and the perception of light may yet return.

It must be observed that, after extensive hæmorrhage of traumatic origin, not only the aqueous humour, but also the episcleral connective tissue, shows a yellow tinge after some weeks.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

MARTIN-DAMOURETTE AND OTHERS ON THE PHYSIOLOGICAL ANTAGONISM OF POISONOUS SUBSTANCES.—Several memoirs on this subject have lately appeared in France and in Germany. For the following particulars we are indebted to a writer in the *Archives des Sciences* for March 15. (An account of the researches of MM. Rossbach and Fröhlich on the action of atropia and physostigma on the pupil and heart was given in the *London Medical Record* for December 17, 1873.)

M. Martin-Damourette has studied the physiological properties of eserine, the active substance of the Calabar bean (*Physostigma venenosum*), named also physostigmine and calabarine. Having made experiments on rabbits, birds and frogs, he thus sums up its properties as affecting motor organs.

1. It excites the muscles, and produces muscular convulsions, shown in fibrillar contractions, convulsive movements, contractions of the intestine, and lastly, pupillary contraction.
2. It excites the cerebro-spinal motor centres.
3. It diminishes (like curare, but less rapidly), the excitability of nerve-terminations in the muscles.

These three elementary properties appear differently according to the dose given, and especially according to the mode of administration. While a large dose of the poison quickly produces convulsions, paralysis of the phrenic nerves, and death by asphyxia, in warm-blooded animals, it is possible, by using divided doses (*refractées*), to destroy muscular contractility, without producing the nervous excitation, which, in the former case, caused death. These two actions M. Martin-Damourette regards as a sort of antagonism established between the two principal physiological properties of the substance; the muscular paresis being opposed to the death by nervous excitation. It is in this way that he is led to explain the success which some authors have said they met with in using the Calabar bean for treatment of tetanus. He insists on the necessity of using divided doses in the treatment of tetanus, in order to obtain muscular relaxation. 'Weak and gradually increasing doses of sulphate of eserine,' he says, 'are a certain means of developing this antagonism to advantage of neuro-paralytic effect, and hence results a tolerance of doses which are more than toxic, capable of relaxing the tetanised muscles.' In

the continuation of his memoir, M. Martin-Damourette seeks to prove that an analogous influence is brought into play, when (as Dr. Fraser shows) the toxic action of eserine is neutralised by a small dose of atropine. Atropine, in small doses, has thus neuro-paralytic properties capable of arresting the convulsive action of eserine.

One of the important properties of eserine is that of making the pupil contract, either when applied locally to the ocular globe, or when, through absorption, it penetrates into the aqueous humour. This property, often utilised in treating mydriasis produced by atropine, has received very various interpretations; some explaining the phenomena by paralysis of the sympathetic and the dilator of the pupil (M. Rosenthal, M. Bernstein-Dogiel); others (M. Grünhagen) by excitation of the terminations of the common oculo-motor in the sphincter of the iris; others, again, by a combined action of both these agents. This question has also occupied M. Martin-Damourette, and it has been one of the principal subjects of study by MM. Rossbach and Fröhlich (in a memoir named), who have limited their researches to the physiological action of physostigmine and of atropine on the iris and the heart.

Like MM. Rossbach and Fröhlich, M. Martin-Damourette remarks (a fact already pointed out by M. Grünhagen) that a slight excitation of the cervical sympathetic produces dilatation of the pupil contracted by eserine; the nerve is not then paralysed.

M. Martin-Damourette thinks also that the irritation of the third pair (which furnishes the ciliary nerves governing the contraction of the sphincter) is not the cause of myosis (a view which, on the other hand, MM. Fröhlich and Rossbach accept). The contraction of the pupil takes place even when the common ocular motor is paralysed by atropine or otherwise; whence M. Martin-Damourette concludes that eserine acts directly on the constrictor muscle of the pupil, as on the other muscles.

According to M. Köhler (in a recent memoir), the antagonism of Calabar bean and of atropine only exists in warm-blooded animals, and is not observable in the frog. It is the same with saponine, which has an antagonistic action to Calabar bean. In the frog, as M. Roher has also shown, the Calabar bean paralyses the accelerator fibres of movement of the heart, and does not act on the musculo-motor ganglia of that organ.

M. Köhler makes also a comparative study of various poisons which act on the heart and modify its rhythm in different ways. Analysing the action of these poisons, he seeks to demonstrate that the phenomenon of arrhythmia, studied by Heidenhain, is due to irritation of the muscles of the heart by blood containing an irritant poison, which brings on a momentary fatigue and relaxation, atony of the ventricular muscles.

According to this author, Calabar bean does not produce arrhythmia, because it leaves intact till death the cardiac muscles and ganglia, and it may even stop the arrhythmia produced by injections of saponine and of atropine. This interpretation of arrhythmia is different from the one adopted by Heidenhain.

We have next M. Luciani's researches made in the laboratory, and under the direction, of M. Ludwig. The author proposes to study, with the aid of the graphic method, the contractions of a frog's heart separated from the body. He gives a drawing of the registering apparatus used; it consisted of a transmission-manometer, connected with the heart,

which was filled with serum, and in which a determinate pressure was produced. A style connected with the manometer registered on a cylinder the oscillations of the mercury. The author used in his experiments (following the example of Dr. Bowditch, who has experimented in the same direction), a heart stopped in diastole by a ligature applied at the level of the sinus of the vena cava; he investigates the influence of a change of temperature, of pressure, ligature, &c., on the heart. Subjecting the organ to the influence of various poisons (muscarine, atropine, nicotine), he examines into the causes governing the periodic action of the heart. From a study of the curves obtained, and analysis of his numerous experiments, the author concludes, it cannot be admitted, as a large number of authors suppose (in particular Böhm, Schneideberg, Köhler, &c.) that there are in the heart different centres, some of which produce arrest of the heart, the others excitation of its movements. According to him, there is only one automatic centre, which can be modified in different ways by exterior and toxic agents.

ALEX. B. MACDOWALL.

COYNE ON THE STRUCTURE OF THE MUCOUS MEMBRANE OF THE LARYNX.—P. Coyne (*Archives de Physiologie*, vol. vi. p. 92) has arrived at the following conclusions upon this subject. The mucous membrane of the larynx is formed in a layer subjacent to the epithelium, by a reticulated tissue analogous to lymphatic tissue; it thus approaches the structure of the mucous membrane of the small intestine. Lymphatic organs, analogous to the closed sacs of the small intestine, exist in the superficial layers of the mucous membrane. The author is of opinion that the presence of these glands may account for the development of certain ulcerations in the larynx during fever, as in typhoid. On the free border of the inferior vocal cord, certain vascular, and probably nervous papillæ, are to be found. These papillæ are specially developed on the anterior half of the vocal cords. From the preparation of more than twenty-five human larynges, the author has satisfied himself that the submucous serous sac, admitted by Fournié, does not exist.

PATHOLOGY.

STICH ON THE PATHOLOGY OF TUMOURS.—Dr. Edward Stich of Nürnberg (*Berliner Klinische Wochenschrift*, Nov. 23, 1873, *et seq.*) draws attention to the theory of origin of tumours from mechanical injuries, a subject which he considers somewhat neglected. He commences by briefly reviewing the well-known arguments for and against the constitutional origin of tumours, inclining himself to believe in their purely local origin. He draws attention to the fact that tumours are most common in parts most exposed to mechanical injuries, such as the natural orifices of the body, the narrowest parts of the alimentary canal, &c. He confesses that he has nothing new to add to a subject which has been already so extensively discussed, and which, until some further data are obtained, must still remain to some extent a matter of opinion.

The greater part of the paper is composed of four cases illustrative of the influence of local injuries in the production of tumours. The first is a case of sarcoma of the left occipito-atloid articulation, and of the neck of the fifth rib and the body of the fifth dorsal vertebra. The patient was a healthy blacksmith, aged twenty, who, in consequence of his chair being pulled from under him as a practical joke, fell backwards, striking his head and shoulders violently on the ground. At the time he was stunned, but soon recovered, and was able to walk home. The following day he was tolerably well, with the exception of some pain and stiffness about the neck. He could, however, bend his head backwards and forwards, and rotate it without much difficulty. From this time forwards he had frequent pains in the neck, and lost flesh and appetite. Five months after the accident, when he came under observation, the neck was found to be fixed stiffly, and a tumour could be distinctly felt in the suboccipital region, and another at the level of the fifth dorsal vertebra. These tumours increased rapidly, paralytic symptoms supervened, and he died about six months after the injury. The examination of the body after death showed two soft white sarcomatous tumours, one destroying the neck and head of the fifth rib and extending into the body of the fifth dorsal vertebra, and the other affecting the left lateral mass of the atlas and the left condyle of the occipital bone, extending in the base of the skull as far as the great wing of the sphenoid. The odontoid process was bare, and the ligaments were destroyed. In this case the author considers the primary injury to have been a fracture of the transverse process of the atlas and another of the fifth rib. The growth necessary for the repair of these injuries he believes to have been the starting-point of the tumours—the normal limit of activity being exceeded and a sarcoma produced instead of callus. A somewhat similar case is also recorded in which a sarcoma developed in the base of the skull of a boy twelve years of age, some time after a severe blow on the head. At the *post mortem* examination Dr. Stich found what he considered to be an old fracture of the small wing of the sphenoid. It is unfortunate that the only two cases of sarcoma following fracture that Dr. Stich is able to bring forward should have occurred after injuries, the nature of which was not ascertained at the time of the accident, especially as it is impossible not to look with suspicion on conclusions drawn from bones to a greater or less extent destroyed by a tumour.

The author suggests that the frequency of sarcomata in bones may be due to the liability to mechanical injury to which they are exposed by their rigidity. This suggestion would be of more value if he could bring any statistics to prove that those bones, and those parts of bones most exposed to injury, are the most frequent seats of sarcoma.

The two other cases contained in this paper furnish much clearer evidence of local origin of tumours. In one, a 'scirrhous cancer' developed in a scar left in the lower lip by the kick of a horse, and in the other a fibro-sarcoma, which ultimately reached the size of a foetal head, formed in the abdominal walls of a healthy woman aged thirty-four, directly consequent upon a blow from the horn of a cow.

In a second paper by the same author, we have an account of two interesting species of myxoma which have come under his observation. To one he gives the somewhat complicated name of 'myxolipoma sarcomatosum telangiectodes.' The tumour was situated on the front of the fore-arm in a man aged seventy-three years. It had existed for thirty-six years, and until a short time before had remained stationary at the size of a hazel-nut. It suddenly commenced to grow rapidly, and, at the time of operation, had reached the size of a foetal head. It was found deeply to implicate the muscles, rendering amputation necessary after a partial attempt at removal. On examination after removal the tumour was found to be composed partly of fat as in an ordinary lipoma, partly of the gelatinous basis and stellate cells of a pure myxoma, and partly of excessive vascular round-celled sarcoma tissue.

In the same paper the author records a case in which the left leg was amputated for a large myxoma, reaching from the ankle to the upper third. In both these cases, the author is of opinion that in its earliest stage the tumour was an ordinary lipoma.

MARCUS BECK.

COLOMIATTI ON EPITHELIOMA AFFECTING THE SYMPATHETIC NERVE.—Dr. V. F. Colomiatti describes (*Giornale della Reale Accademia di Medicina di Torino*, January 20, 1874) the *post mortem* appearances shown in a case of epithelioma of the cervix uteri in a woman aged forty. Almost the entire anterior lip of the os tincæ was destroyed, and there was thickening of the posterior lip with ulceration at the sides. The anterior wall of the body of the uterus contained a round tumour of the size of a small nut. The walls of the bladder showed numerous grey white spots, limited to the region of the trigone; and at this point there was thickening of the vesicovaginal septum. There was no ulceration of the mucous membrane of the bladder. The lymphatic glands lying along the vertebral column were much enlarged and hardened, as were also those in the iliac fossæ. The left suprarenal capsule was also large and hard; both it and the glands presented on section a grey white colour. The left semilunar ganglion was as large as a small French bean, and somewhat increased in consistence; the right semilunar ganglion and some other small ganglia were pressed together, and also felt rather hard.

On microscopic examination, the cervical portion of the uterus was found to be the seat of epithelial cancer. The tumour in the anterior wall contained nucleated fibro-cellular cells. On examining the portion of bladder lying nearest the ulcerated portion of the cervix uteri, it was found that the cancer-cells had infiltrated the connective tissue and had invaded

the bladder, among the muscular fibres of which they formed small nodules. The lymphatic glands and the left suprarenal capsule also contained epitheliomatous cells.

The semilunar ganglia were found to be infiltrated with cells of the same character as those of the uterus; they lay among the nervous fibres, and were readily distinguishable from the ganglion-cells. The cancer-cells surrounded the ganglion-cells in layers which compressed and atrophied the latter, reducing them to an indistinct mass of pigment-granules. The nerve-fibres were separated by the cancer-cells, and compressed. In some parts, where there were accumulations of the latter, the nerve-fibres had totally disappeared, the only remaining traces being some very fine fibres of connective tissue united in small fasciculi. In several parts, the cancer-cells formed nodules, and were pressed together so as to assume a polygonal form. Sometimes the cancer-cells only partially surrounded the nerve-fibre; and in other cases they were found within the sheath, having the appearance of being infiltrated. In some of the nerves, the sheath of connective tissue was found to be interrupted here and there, the points of interruption being filled with cancer-cells infiltrated into the sheath and forming small nodules. In some sections, the ganglionic cells were not affected, but the nerve-trunks had cancer-cells within and in the substance of the neurilemma. Some of the nerve-fibres in the uterus also contained cancer-cells within the sheath, sometimes surrounding the nerve-fibrils, sometimes infiltrated among them.

Dr. Colomiatti also describes, in *L'Indipendente* for January 5 and 15, the appearances presented in the pelvic viscera and nerves of a woman who had died of uterine cancer in the S. Luigi hospital.

The cervix uteri was destroyed, the vesico-vaginal septum perforated, and nearly the whole body of the uterus invaded by the disease. Epitheliomatous cells were found on microscopic examination. One of the left lumbar ganglia was harder and larger than that on the opposite side, and among its fibres and ganglion-cells were found cells in all respects similar to those in the uterus, along with cells resembling white blood-corpuscles, and some fusiform cells. Epitheliomatous cells were also found in the connecting branches between the ganglion and the lumbo-aortic plexus, as well as in the ganglia and nerves of the plexus. Similar cells were also found in other portions of the hypogastric plexus.

In the uterus, it was difficult to find the nerves, on account of the destruction of the tissues. In those which were found, the connective tissue sheath was almost entirely destroyed, and the nerve-fibres were infiltrated and atrophied by the cells. In some rare instances, the cells lay between two layers of the sheath, of which the inner was the thinnest. This appearance was also seen in some portions of the lumbo-aortic plexus. Nerves affected in the same way were found in the connective tissue between the bladder and uterus, and also in the left broad ligament. In some parts, also, the nerve-sheaths were infiltrated with migrated corpuscles.

A. HENRY, M.D.

ENGLISCH ON CYSTS OF THE POSTERIOR WALL OF THE BLADDER IN MAN.—In the *Anzeiger der k.k. Gesellschaft der Aertze in Wien*, January 1874, Dr. Englisch has a communication on these tumours. If a sufficient number of preparations be examined, there are not unfrequently found, in the space between

the two vasa deferentia, and less often on the vesiculæ seminales, cysts of various sizes. He describes them as consisting of four different kinds.

The first class of cysts corresponds with the mesial line, and lies in the musculo-fibrous membrane, which binds together the vasa deferentia.

The second kind lies more to the side, near the vas deferens, and is connected with it by means of a process of connective tissue.

The third form lies partially in the prostate, and corresponds with an enlarged sinus pocularis, if its orifice be closed.

A fourth form is connected with the vesicula seminalis, and has no attachment to the vas deferens.

These cysts do not only exist in adults, but are also met with in children, and it has been clearly shown that the first three kinds exist in newly born infants, and become developed later on.

It is probable that the cyst lying in the middle line corresponds with the remains of the Müllerian canals, and that those of the second form proceed from the development of the orifice of the vas deferens, or represent the remains of the cul-de-sac of the Wolffian body.

The third form is developed when the cul-de-sac of the sinus pocularis, which commences at the colliculus, extends far backwards, and becomes distended.

The fourth species is found in connection with the results of inflammation of the vesiculæ seminales, so that the closure of a sinus is peculiarly a result of an inflammatory process.

So long as the cysts are small, they cause no particular annoyance, although they may, as in instances proved, distend the recto-vesical pouch and cause retention of urine.

EDWARD BELLAMY.

DOUTRELEPONT ON A RARE FORM OF SCIRRHUS OF THE MALE BREAST.—Professor Doutrelepont (*Berliner Medicinische Wochenschrift*, March 14) relates a case of a rare form of scirrhus of the male breast (squirithe pustuleux ou disséminé of Velpeau). Carcinoma of the male breast is very uncommon, and this particular form still more so. The patient was fifty years old, weak and sickly looking. In 1870 he first noticed a hard swelling in his left nipple which, however, did not cause much pain. It was treated with iodine ointment. In 1872 he first felt pain from the pressure of his braces, and from that time there was a general enlargement of the swelling. In February, 1873, it ulcerated and spread. This was treated with nitrate of silver. In May, when he first came under observation, the mass had become attached to the ribs. The ulcerated surface was somewhat circular, and had a diameter of about 2½ inches. The base was very much excavated, cicatrised at one little spot, and very hard. There were several hard knots in the skin, and at the edge of the axilla was a movable mass, as large as a pigeon's egg. At the edge of the sternum and close to the xiphoid process, there were two knots attached to the cartilages, and a good many of the axillary glands were enlarged and hard; between this time and July a dozen new tumours had appeared. The ulcer was treated, after Burrow's method, with powdered chlorate of potash.

Two contiguous tumours were removed, and a microscopical examination showed scirrhus. In the proximity of these tumours there was a cell-infiltration through the entire skin in the form of canals, which ran obliquely to the surface, in different places

irregularly dilated, ramifying, and, on closer examination, leaving no doubt that they were in connection with the lymphatics of the skin. Where this cell-infiltration involved the epithelium of the glands of the skin or of the epidermis, great proliferation was manifested. It is probable that the scirrhus in this case spread through the lymphatics of the skin.

EDWARD BELLAMY.

FELTZ AND RITTER ON AMMONIÆMIA.—The authors record, in the *Comptes Rendus*, experiments from which they deduce that urine in affections of the genito-urinary apparatus is very rarely ammoniacal. In the immense majority of cases of alkaliescence, the default is considered to be in the want of cleanliness of the vessels employed, these containing albuminoid substances more or less changed.

SURGERY.

SCHELL ON OPERATION ON FISTULA IN ANO WITH THE ELASTIC LIGATURE.—Dr. H. S. Schell describes in the *Philadelphia Medical Times* for February 28, a case in which he operated on fistula in ano by the elastic ligature. The patient was a man, Michael D., aged thirty-six. The fistula, which had existed for several years, was small, opening in the skin about half-an-inch from the verge of the anus, and within the bowel somewhat over an inch from its termination, embracing but little more than the external sphincter ani. The ligature was drawn through the fistula by means of an ordinary eyed probe, brought down outside the rectum, and tied pretty tightly.

An opium suppository was prescribed, to be used in case any pain followed the constriction of the parts. The patient, however, stated that he had no pain at all, and went about the ward as long as he remained in it, assisting the nurse in the care of the other patients. The ligature came away at stool on the fourth day, leaving a granulating wound, to which no further attention was paid, except as to cleanliness, and which healed in the usual manner.

Dr. Schell remarks that the advantages to be derived from the employment of the elastic ligature in this operation appear to be the following. 1. There is no pain. 2. Hæmorrhage is entirely avoided. 3. There is no need of confinement to bed. 4. The bowels may be left to their ordinary regular habits.

The best ligature is composed of three strands of caoutchouc, somewhat compressed within a plaited envelope of white silk into a round cord, and has the strength of an ordinary ligature. The quality of the

article may be judged by smartly stretching an inch or so several times; if unreliable, the gum will crack in various places and slightly project between the threads of the silk, giving the cord a rough, half-broken appearance. A good article has a soft, elastic feel, while the bad is hard and stiff. It is better not to keep much on hand at a time, as the gum finally becomes hard and brittle.

PACKARD ON A SPLINT FOR THE TREATMENT OF EXCISION OF THE KNEE-JOINT.—At a meeting of the New York County Medical Society, on February 23 (*Philadelphia Medical and Surgical Reporter*, March 21), Dr. Packard showed a splint which he had devised for the after-treatment of excision of the knee-joint. The splint at first sight looks like a straight posterior splint for fracture, with two high iron handles at the knee. Instead, however, of being in one piece it is in three pieces, and the handles are iron brackets connecting the upper with the lower section. The middle piece is about four inches in width, and slides between the brackets so as to make the splint continuous. The advantage in this middle section is to afford facility in removing the dressings. The splint when adapted extends up as far as the trochanter major and tuberosity of the ischium; at the lower extremity is an adjustable foot-piece for securing the limb below. The thigh and leg portions of the splint are hollowed out, and to their edges are secured leather sides, which may be perforated by eyelets, and the whole limb in this manner securely fastened. When it is necessary to change the dressing, the limb is elevated and the flat middle shelf slid out. After the dressings are rearranged, this shelf is put back again into position and the limb arranged in bed.

The advantage derived from the apparatus is, that after the operation the ends of the bones may be put in apposition and kept there for an indefinite time, unaffected by the shifting of the dressings. Dr. Packard said also that he found it advantageous after operation to place the limb in such a position that there would be a slight bend at the knee. A more satisfactory result was obtained in this way for the patient, than if the limb were perfectly straight.

Dr. Frank H. Hamilton said that he had found the splint wonderfully adapted for the purpose intended, and withal simple. He was of opinion that it might be of service in some severe cases of fractures, and in some cases of lacerated wounds where it was desirable to keep the parts in a state of rest.

Dr. Lewis A. Sayre also thought highly of the apparatus. It was simple, and well designed for the purpose intended.

CASELLI ON LIGATURE OF THE DEEP FEMORAL ARTERY.—Professor Azzio Caselli recommends (*Bullettino delle Scienze Mediche*, December, 1873), ligature of the deep femoral artery in cases where this vessel, or one of its branches, is wounded and also where it supplies a large tumour of the thigh with blood. The operation, which was suggested to him by the failures that have attended ligature of the common femoral, is performed in the following manner.

An incision, through the skin only, $2\frac{3}{4}$ inches long in thin, and 3 or 4 inches long in fat subjects, is made from the crural arch outside the line of incision for ligature of the common femoral artery. The panniculus adiposus is carefully cut through, and the internal saphenous vein is isolated and turned inwards. The aponeurosis of the fascia lata is

divided on a director, and the crural artery and nerve are exposed by tearing the cellular tissue; the vessel and nerve—the loose cellular tissue between them being torn through with a director—are held apart, and the deep femoral artery is exposed and tied.

Dr. Caselli performed this operation in a case of large tumour occupying the two upper thirds of the inner and posterior part of the thigh, before removing the tumour. The ligature was applied about four-fifths of an inch from the common femoral artery, just above the origin of the external circumflex. The operation was performed with ease, and there was not much hæmorrhage. The patient died, however, of ichorrhæmia at the end of fifty-five hours.

A. HENRY, M.D.

RAVOTH ON UMBILICAL AND VENTRAL HERNIÆ.
Ravoth (*Berliner Klinische Wochenschrift*, March 23, 1874), says that women who have repeatedly borne children, and are subsequently troubled with obesity, for the most part suffer from umbilical rupture, and as a rule neglect it. Hence they frequently present themselves for the treatment of irreducible omental herniæ. In such cases, Herr Ravoth attempts reduction, and if not successful, he applies a large hollow pad, fixed either by means of a band, or by two leather braces, crossing behind. One great difficulty occurs when, as it frequently does, a fresh loop of intestine comes down by the side of this protrusion, and becomes constricted. It is then extremely difficult to diagnose the position of this new portion of gut, and then it becomes an urgent matter whether its reduction should be attempted by the rational taxis. In such a case a peculiarly tense, partially isolated, painful, as it were secondary swelling, must be separated from the original mass very carefully.

The new protrusion rarely lies in the canal of the original one, but is generally to one side of it. It may also happen that this kind of rupture may have other outlets. In doubtful cases, as is customary, operation should be resorted to, and, if possible, without opening the sac. Finally, Ravoth calls attention to the great inclination to a relapse of strangulation, and thinks that treatment by means of the concave pad would prevent this condition. The question as to what sort of truss would best answer the purpose, must depend on the form of the abdomen and the locality of the hernia; and its shape and nature must be taken into consideration, as, without these, a suitable support cannot be obtained.

E. BELLAMY.

LANGER ON DISLOCATION OF THE THUMB AT THE METACARPO-PHALANGEAL ARTICULATION.—Dr. Langer (*Allgemeine Wiener Medizinische Zeitung*, March 3, 1874) describes the results of some experiments on this dislocation. He induced the luxation on the dead body, and, after having frozen the parts and sawn them through, made the following observations. He distinguishes an incomplete and a complete luxation; the latter is when the base of the first phalanx is dragged up upon the head of the metacarpal bone. The obstacle to reduction is due to two factors, ligaments and muscles. His remarks refer to this form of the accident. Complete rupture of the loose capsular ligament invariably occurs, and of both lateral ligaments obliquely.

Dupuytren and Günther advised the subcutaneous section of the latter, since they form, with the volar part of the capsule and the sesamoid bones, an

obstructing ring: this holds good for the incomplete, never in the complete form, which, as Dr. Langer states, occasions complete rupture of the capsular and lateral ligaments.

Further obstacles to reduction moreover exist in that, by the upward dragging of the phalanx, the two interposed sesamoid bones fix themselves firmly on the articular edge of the head of the metacarpal bone, that there a loose portion of the capsule is turned over, and that, in place of the normal horizontal direction, the muscles of the thumb come to lie in an oblique, indeed nearly vertical direction to their insertion on the other side of the joint, whereby they fix the phalanx in this new position.

The treatment must consist of either powerful extension, forced flexion, or the so-called impulsion (*i.e.*, forward pressure against the base of the phalanx, at the same time powerfully dragging it back) and, failing either of these, operation. This consists in making an incision in the volar surface, and removing a piece of the head of the bone, with, if necessary, the sesamoid bones also, and finally fixing the thumb by means of a splint.

EDWARD BELLAMY.

ROSENBERGER ON SPONTANEOUS FRACTURE OF THE FEMUR FROM CARIES AND REUNION BY NEW BONE.—Dr. Rosenberger describes a case (*Berliner Klinische Wochenschrift*, April 6, 1874) occurring in the hospital practice of Dr. Linhart of Würzburg. The patient was a boy fourteen years old, hitherto perfectly healthy and with no sign of scrofula, and who was the subject of osteitis of the lower end of the femur. The abscess was first opened nine days after he first noticed pain in the part. The suppuration was very profuse. The patient was in such a condition that amputation was proposed, but he would not consent to its being done. Two months afterwards, an examination was made under chloroform. The fistulous opening which remained from the previous incision was cedematous and its edges everted. No fluctuation could be felt; nevertheless, Professor Linhart made a fresh incision in order to see the condition of the bone, and possibly find an abscess in it. The result was remarkable. The pus-cavity, in the midst of which, when the original abscess was opened, the bone was felt to be denuded of periosteum so far as the finger could reach, was found to be reformed. The bone was covered again by periosteum, and attached to its surrounding muscles. It was, however, otherwise at the point where the incision had been made. Here the caries had spread so far that there was complete destruction of the continuity of the bone. There was no retention of pus. The limb was placed in a splint. The patient had severe constitutional disturbance, threatening of suppuration in the joint, and symptoms of pyæmia. He, however, by degrees recovered. Frequent examination of the bone showed a general thickening at the point of fracture. Six weeks after the second incision the splint was taken off, and the patient was, without much difficulty, able to straighten his limb. At the time of the report, he could move and lift the leg readily and without any pain. A little carious bone could be felt through a fistulous track.

The treatment of this case is not properly at an end as yet, but it is so far already complete as to be considered so, and worthy to be recorded. Dr. Rosenberger states that a case of fracture from osteitis without any direct dyscrasia, is unknown to him.

EDWARD BELLAMY.

BELL ON ASPIRATION IN RETENTION OF URINE. Dr. Joseph Bell relates an instructive case (*Edinburgh Medical Journal*, April, 1874), and adds: Cases admitting or requiring this treatment will not likely be very frequent—indeed, I have not met with another out of a very large number of stricture cases seen since June; still, in this one, any other treatment would have been very dangerous.

Perineal section is always tedious, requiring chloroform, which the weak heart and emphysematous lungs and diseased kidneys would have borne ill; besides, perineal section has its own dangers in old exhausted subjects. Tapping by rectum would have been difficult, from the enlarged prostate. Catheterisation had failed. The operation was painless, and left no trace. I have a very strong feeling that in similar cases, the aspirator gives us an easy, safe, and reliable means of tiding over a difficulty, emptying the bladder, and thus giving time for other treatment.

It is possible, if necessary, to repeat the aspiration frequently in the same region, but not exactly in the same situation.

The special merit of the aspirator here is, that it enables us, by the suction-power it possesses, to withdraw the urine through a tube little larger than an acupuncture needle, the wound inflicted by which heals up at once and leaves no trace.

MATERIA MEDICA AND THERAPEUTICS.

MCGAUGHEY ON THE USE OF GELSEMINUM IN INTERMITTENT FEVER.—Dr. J. D. McGaughey, of Wallingford, Connecticut, writes as follows in the *Philadelphia Medical Times* for March 7, on the use of gelseminum in intermittent fever.

'Every physician who has had to deal with intermittent fever has met with cases of a regular paroxysmal form, quotidian, tertian, or otherwise, easily controlled by quinine; yet after a certain length of time the paroxysms return again and again, necessitating larger antiperiodic doses, until the alkaloid

has become useful only in preventing for a short time the attack, having lost its curative powers altogether. In such cases, gelseminum shows its antimalarial powers to a gratifying extent. If, after taking, as it were, a new start in the treatment of such a variety of intermittent fever, we attend to any congestion of inaction that may be lurking about the abdominal viscera, and combine quinine with gelseminum, and give them until the latter produces its physiological effects, the inveterate catenation of morbid action will be broken in upon without failure in almost every case, and there will be but little danger of relapse until the subsequent season. Of course, it will fail to produce the desired effect in a small percentage of cases.

'A second variety is where, in the beginning of autumn, the malarial cases lose their regular paroxysmal form, and are characterised by irregular chills and sweats—a partial paroxysm sometimes occurring in the morning or afternoon—occasionally alternate fever and sweating during the night; loaded tongue; pains in the bones and joints all over the body; headache; anorexia; nausea; high-coloured urine; occasional dysenteric symptoms; malaise, &c. If quinine have been used alone in these cases without any amelioration of symptoms, the vagary of malaria still holding its curious anomalous course, gelseminum, added to the treatment, and pushed to considerable weakness of eyelids, will generally conquer the disease in a short time.

'I feel pretty well assured that, if physicians will give gelseminum a fair trial in connection with quinine, in cases where quinine alone has failed to cure, they will meet with gratifying success; provided they push the gelseminum until its physiological effects are produced. I think it is of prime importance, in all cases of malarial fever, to attend strictly to the condition of the abdominal viscera—to keep the eliminative organs, bowels and kidneys, in a state of activity. It is to the neglect of such precautions that we are to attribute so many failures in administering quinine. I paid attention to this point in the treatment of about one hundred and twenty-five cases of intermittent fever which have come under my observation in the past two years, and I am fully convinced that, if we ignore the condition of the abdominal viscera, and recklessly rely upon the antimalarial powers of quinine alone, or its accessories, the fame of cinchona as a specific will never be vindicated or realised.'

MILLER ON TRAUMATIC TETANUS TREATED BY HYPODERMIC INJECTION OF ATROPIA: RECOVERY.—At a recent meeting of the Wayne County (Illinois) Medical Society (*Philadelphia Medical and Surgical Reporter*, March 21) Dr. Miller reported the case of a man whom he saw on December 24, two weeks after the accident. The patient had received a gun-shot wound on the hand, the ball entering the palmar surface, carrying away the larger portion of the fourth and fifth metacarpal bones. The patient was exposed on the 28th, during a sudden change of the weather, and immediately afterward he was seized with rigidity of the muscles. Hydrate of chloral was given, but without relieving the spasm.

Dr. Prince was called in consultation the next day. He suggested the hypodermic injection of one-sixtieth of a grain of sulphate of atropia. An immediate amendment of symptoms followed the first injection. The chloral was continued, with an in-

jection of atropia twice daily, for about four weeks. Whenever the effect of the medicines passed away, the violent spasmodic condition returned. The patient always expressed himself as greatly relieved by the hypodermic injection. The pulse ranged during this time from 112 to 120. On January 29, there were marked symptoms of improvement, from which time convalescence uninterruptedly continued.

BOULEY AND BÉHIER ON TRANSFUSION OF BLOOD.—An interesting case of transfusion was recently recorded in the archives of the Paris Academy of Sciences, by M. Béhier. At the moment before M. Béhier completed transfusion, the patient seemed menaced with instant death. The pulse was imperceptible, and the faculties in a corresponding state. M. Béhier, dwelling upon the facts of the case, insists especially upon the necessity of injecting blood as it occurs in nature, without previous defibrination or lowering of temperature. The preliminary operations, intended to prevent coagulation of the fibrin, are useless when the operation is performed promptly, which is easy. M. Béhier insists upon the injection of living blood, with its corpuscles unaltered by beating or refrigeration, and besides containing intact the albuminoid matters whose nutritive value is considerable. M. Béhier also insists upon the possibility of simplifying one of the most important of the manual operations. One of the difficulties is the introduction into the vein of the cannula or trocar conveying the blood. Nélaton, to obviate this inconvenience, proposed an incision at the level of the vein, to an extent of two to three centimètres (.78 to 1.1 inch). Béhier advises opening the vein with a mandril, or instrument such as will make an incision suitable to the size of the cannula to be introduced. It is further advised that the blood be introduced slowly and in small quantities at a time. The transfusion ultimately was highly successful, and the patient was discharged perfectly cured. Baron Larrey declares very strongly in favour of this system, by which two operations, as formerly, are now reduced to one.

In a paper immediately presented to the Academy, M. Bouley further describes the instrument advised by M. Béhier, that known as invented by M. Moncoq. This apparatus consists essentially of a syringe, the body of which is of crystal-glass, the piston being worked by a graduated wheel. Alternate motions of a quarter of a turn being given to this wheel, the piston is raised and lowered, and thus to the liquid blood regular impulses are communicated, imitating those which result from the beating of the heart. Originally, M. Moncoq transfused with the aid of two caoutchouc tubes, one of which communicated with the person from whom blood was drawn, the other with the patient who was to receive the blood. The last modification nearly realises perfection. This modification consists in the adaptation of a small cup to the inferior portion of the body of the pump. This cup, of small diameter, is applied, inverted, upon the vein whence blood is to be extracted. The blood drawn into the cup is carried into the body of the pump, and thence transferred to the recipient vein.

PAGET HIGGS, D.Sc.

BOND ON A PALATABLE DRINK OF CASTOR OIL.—Dr. H. Treverton Bond, writing to the *Druggists' Circular*, recommends the following plan of dispensing castor oil and converting it into a palatable drink. Pour into a tumbler about six drachms of syrup of sarsaparilla, add a small quantity (about 20 grains) of bicarbonate of soda, stir with a

spatula, add about a tea-spoonful of a saturated solution of tartaric acid, and again stir well; this produces a heavy viscid froth. Pour down the side of the tumbler, so as to sink to the bottom and not mix with the froth, about an ounce of water; then add the oil. The whole is to be drunk without agitation. The water is at the bottom, the oil in the centre, and the froth on the top. The drink so prepared is said to be tasteless, and the oil is all taken, as, after dispensing, the glass can be washed clean with water, showing that no grease adheres to its sides.

PUBLIC HEALTH.

BELL ON THE ADULTERATIONS OF STARCHES, TEA, AND COFFEE.—On Thursday, February 19, Mr. James Bell (of the Inland Revenue Office) delivered a lecture before the members of the Chemical Society, at Burlington House, on 'The Detection of Adulteration in Food and Drink.' The chair was taken by Dr. Odling, F.R.S., the President of the Society.

Mr. Bell commenced by observing that he should confine himself chiefly to an examination of those articles, the detection of adulterants of which required the use of the microscope. They were more interesting than those which required a chemical examination.

He considered it most important that chemists, qualifying themselves as public analysts, should be thoroughly acquainted with the characteristics of different starches used in adulteration. They comprised wheat, barley, oats, rye, maize, potatoes, peas, beans, sago, and arrow-root, and were used to adulterate mustard, cocoa, coffee, spices, &c. The cheaper starches were either mixed with or substituted for the dearer starches. Potato-starch was substituted for true arrow-root; bean-flour for other flour; and oatmeal was adulterated with barley. When starch was examined under the microscope, it was found to consist of minute granules. Diagrams of the various granules in the starches were here exhibited and explained by the lecturer, who showed the difference between them in size, shape, and appearance.

The adulteration of coffee had given rise to much discussion. It was only when roasted and ground that it could be adulterated successfully. A simple way to detect adulteration in coffee was to place some in water in a test-tube, and in five minutes its presence would be detected. If infusions of equal quantities of chicory and coffee were placed in tubes, the colour of the chicory infusion would be twice as deep as of the coffee infusion. By the aid of the microscope the presence of chicory could be ascertained, and by the density of its infusion the quantity was known. Even 5 per cent. of adulterating matter in coffee could be detected. The husk of coffee-berry was removed, and it was the bean only that was brought into this country. Inside the husk was

the parchment, and inside that the skin which enveloped the bean. A portion of skin came with the bean, because more or less of it was contained in the folds of coffee-bean. The various tissues of the coffee-bean were then described by Mr. Bell; who afterwards said that the law allowed chicory or any vegetable substance to be substituted either for coffee or chicory, provided that a duty had been paid upon the article, so that any person was at liberty to prepare any article as an adulterant, provided he paid a duty upon it. If vegetable matter were used, it must be grown in the United Kingdom. Coffee was so peculiar in its vegetable structure, however, that there was no difficulty in detecting seeds used as adulterants, or in identifying the seeds. Locust-beans had also been found in coffee to the extent of 30 per cent. Rye had also been used to adulterate coffee; and when roasted and ground, there were always some starch-granules remaining. Its presence could be detected both by the granules, and by the character of its husks. Venetian red had been used to colour both chicory and coffee, and black mustard for chicory.

The practice of adulterating tea dated back many years. The character of adulteration was now entirely different from what it had been; and it was effected before the importation of the tea. Exhausted tea leaves were prepared in China, where the chief adulteration was carried on for the purpose of imparting a green tint, so much desired by the people of this country. Tea, in China, was adulterated with magnetic oxide of iron. To separate the tea, it should be ground into powder, and then a magnet moved over it would draw along with it all the oxide of iron. The practice of manufacturing tea from exhausted leaves in this country was almost discontinued; at least, there had been no complaints made about it. In the preparation of exhausted tea-leaves, the leaves were twisted into their proper form by the use of gum. Black tea was adulterated with black lead. Mr. Bell described minutely the face, serrations, skin, leaves with long hairs on them, the form of cells and the cell-walls, &c., of tea and some of its adulterants. The best way to examine samples was to put them in water; the damp leaves should then be opened and expanded, placed on a glass slide, and first examined with the naked eye, and afterwards with the microscope. After a little practice, a person would have slight difficulty in determining whether a leaf was a tea-leaf or not. The Chinese used also quartz as an adulterant, and tea had been found to contain as much as 200 per cent. Nine per cent. of oxide of iron had also been found in some tea. The colouring of tea was done chiefly with soap-stone. In this country, at one time, a variety of substances was used for the facing of green tea. Many of them were poisonous substances. As a rule the favourite article now used for that purpose was a mixture of Dutch pitch and Prussian blue. The easiest way to detect the latter was by means of the microscope, under which the angular crystals were seen, and the particles of pitch turned brown. Black lead, under the same test, presented a very lustrous appearance; there was a complete absence of any structure. As to exhausted tea-leaves, the means hitherto adopted to determine their presence, was to ascertain the quantity of insoluble matter, gum, and tannin. Old leaves were known by their rough surfaces. Young leaves were clothed with hairs, both on the upper and lower surfaces. The most reliable data to

determine the quantity of exhausted tea-leaves was the presence of gum, which sometimes was found deficient in quantity, and at other times in excessive proportions.

The lecturer concluded by treating briefly of pepper and mustard.

MISCELLANY.

A CHILDREN'S HOSPITAL is to be erected in Alservorstadt, a suburb of Vienna. A lady named Karoline Riedl, recently dead, has bequeathed 100,000 florins (10,000*l.*) for this purpose.

DISTRICT MORTUARIES.—The vestries of Marylebone, Paddington, and St. Martin's in the Fields, have already adopted the very necessary step of providing a parish mortuary, and we are glad to find that St. Mary, Islington, has this week followed the example. These mortuaries are fitted with air-tight glass coffins, and the proper appliances for the performance of *post mortem* examinations. Where, as in Clerkenwell, this provision is not made, the poor have to suffer, especially in cases of inquests, the most revolting hardships.

A DIPLOMATIC CONGRESS.—We have authority to state that a diplomatic Congress relative to the treatment of prisoners of war, in which nearly all the European Governments will be equally represented, will take place in Paris early in May. The preliminaries of the Congress have been arranged by the *Alliance Universelle*, and judging from the care with which the *projet de règlement* has been prepared, and from the willingness which the Great Powers have shown to give diplomatic assistance in discussing it, there is reason to hope that a satisfactory result may be obtained.

THE ALLEGED DEGENERACY OF THE HUMAN RACE. Dr. J. M. DaCosta, in his late valedictory address to the Graduating Class of the Jefferson Medical College in Philadelphia, remarks as follows: 'What we hear of the physical degeneration of our race is very doubtful. I think the men as well-formed and as capable of continued exertion as ever. When we call to mind the marches of the British troops in India and Abyssinia, or of the Prussians in their late campaign; when we reflect on the splendid heroism, the privations endured, the extraordinary vigour of the men, both from the North and South, who were citizens one day, soldiers another, and who, brethren again, have raised the American name into a synonym for determination and endurance, it takes very strong faith to believe that the men of the second half of the nineteenth century are degenerating.'

CHOLERA IN ITALY.—A letter from Dr. Maragliana, sanitary commissioner, to the *Movimento* of Genoa, shows that since the end of February the cholera has revived in the five provinces where it had already claimed a certain number of victims. These provinces are respectively Vernazza, Monterosso, Manarola, and Riomaggiore. The disease reappeared in consequence of great earthworks in connection with the railway, which brought together four thousand workmen, placed under the most deplorable sanitary conditions. It has been found necessary to disperse them by force, and to isolate the cholera patients and their families. The cholera has also made its appearance in Genoa and in different parts of Liguria. It has made its way from Vergatto to Porretta, and thus threatens to invade the centre of Italy. Professor Brugnoli and Dr. Rosi, commissioned by the provincial Council to inform themselves of its progress, have adopted rigorous measures for the isolation of the cholera-patients, having verified the deaths of three persons from this disease, which appears to have been imported by the labourers of Vernazza. Great precautions are therefore held to be necessary.

TRICHINOSIS.—In Gossengrün, a small town in Bohemia, sixty persons have been affected with trichinosis from eating diseased pork, and six have already died. There have also been recently some cases in the hospital at Pesth.

THE GERMAN UNIVERSITIES.—Professor von Recklinghausen, now of Strasburg, has been invited to the chair of Pathological Anatomy in Vienna, in the room of Professor Rokitsansky. Dr. Köster, of Giessen, has been chosen professor of Pathological Anatomy in Bonn, in the room of Professor Rindfleisch, who goes to Wurzburg.

ANCIENT RECIPES.—The *Philadelphia Medical and Surgical Reporter* quotes the following curious letter, taken originally from the *Carolina Gazette*, of May 9, 1750 :—
‘To the Printer—Sir, I am commanded by the Commons House of Assembly to send you the enclosed, which you are to print in the *Carolina Gazette* as soon as possible. It is the negro Caesar’s cure for poison, for discovering of which, and likewise his cure for the bite of a rattlesnake, the General Assembly hath thought fit to purchase his freedom and grant him an allowance of 100*l.* per annum, during life. I am, &c., JAMES IRVING. Take the roots of plantain and wild hoarhound, fresh or dried, three ounces; boil them together in two quarts of water to one quart, and strain it; of this decoction let the patient take one-third part three mornings, fasting, successively, from which, if he finds any relief, it must be continued until he is perfectly recovered: on the contrary, if he finds no alteration after the third dose, it is a sign that the patient has not been poisoned at all, or that it has been with such poison as Caesar’s antidotes will not remedy, so he may leave off the decoction.’

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17*s.* 4*d.*; free by post, 19*s.* 6*d.*

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2*s.* 6*d.* each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready price 19*s.* 6*d.* Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1*s.* 6*d.* each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD :—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM’S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o’clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, APRIL 29, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

DOGIEL ON THE PHYSIOLOGICAL ACTION OF ALCOHOL.

In a paper on monatomic alcohols in their pharmacological relations, read before the meeting of Russian *savants* at Kasan in 1873 (Pflüger's *Archiv*, vol. viii. part 11, 12) J. Dogiel arrives at the following results.

1. Ethyl-alcohol, when introduced into the stomach, is not only absorbed by the veins, but also by the lacteals. The alcohol can be detected in the chyle of the thoracic duct, as well as in the serous and arterial blood, in about a minute and a half after its introduction.

2. The excretion of the alcohol from the organism, apart from the ways already known, occurs also through the skin in frogs.

3. Ethyl-alcohol acts chiefly, not through reduction in the blood, not through the oxydation-products of the alcohol in the blood (certainly not through aldehyd or acetic acid), but as alcohol.

4. The action of alcohol on blood obtained from an artery is very different, both in relation to its coagulation, and to the escape of hæmoglobin from the blood-corpuscles and its crystallisation, according to the concentration and quantity of the alcohol, and according to the duration of its action and the temperature. Blood drawn from an artery, and treated with alcohol from 40 to 20 per cent. (after Richter) either does not coagulate at all, or only very loosely; whilst alcohol of 97 per cent. causes even defibrinated blood to coagulate. The most favourable circumstances for the preparation of hæmoglobin crystals, is to add to 10 grammes of defibrinated blood, two or three grammes of 97 per cent. alcohol and allow the mixture to stand for twenty-four hours, at a temperature of 57° to 63° Fahr.

5. The crystallisation of hæmoglobin under the influence of alcohol does not depend on the action of oxygen. Blood charged with carbonic oxide or carbonic acid, crystallises almost at the same time with arterial and venous blood.

6. Blood from an animal, which is under the influence of alcohol, coagulates more slowly and yields less fibrine than normal blood.

7. Ethyl-alcohol rapidly causes the amœboid movements of the white corpuscles to cease, and at a certain concentration dissolves both them and the red ones.

8. If ethyl-alcohol be added to blood drawn from an artery, putrefaction is retarded and the development of low organisms prevented. Arterial blood, obtained from an intoxicated animal, decomposes more quickly than normal blood.

9. The action of ethyl-alcohol on the heart-beats

consists in acceleration followed by retardation. Under a strong alcoholic action, the very pronounced retardation of the pulse passes again into acceleration. These phenomena depend on the one hand upon stimulation of the accelerating nerves of the heart, and on the other, on the increased and afterwards diminished excitability of the inhibitory fibres of the pneumogastric nerves. In general, however, the excitability of the accelerating nerves of the heart resists the paralyzing action of the alcohol longer than does the excitability of the pneumogastric nerves. Ethyl-alcohol is not without an effect on the cardiac muscles, which is indicated under certain circumstances by the beats of the heart becoming slower and stronger.

10. The arterial blood-pressure is at first increased and then diminished by the alcohol. The excitability of the vaso-motor centre runs parallel to the blood-pressure. If the blood-pressure have sunk, neither dyspnoea, nor the reflex stimulation of the vaso-motor centre from the central end of the vagus, produces the ordinary effect.

11. The rapidity of the blood-current in the carotid artery is at first increased and then diminished under the influence of alcohol. The greatest retardation of the blood-current coincides with the period of alcoholic narcotism (sleep).

12. Respiration is accelerated when small doses of ethyl-alcohol are introduced into the stomach or injected into a vein of the leg; with larger doses it is, however, rendered slow. The depth and rhythm of the respiration also vary. The slow respiration is at the same time superficial. Inspiration becomes longer. The reflex action from the vagus on the respiratory centre, which is generally evidenced by an acceleration of the respiration, becomes weaker, according to the degree to which the intoxication increases. If alcohol be injected into the jugular vein in the direction of the heart, there follows at once, with intact vagi, slowness of respiration; with divided vagi, however, there is acceleration. The change of the respiration under the influence of alcohol depends on its action both on the medulla oblongata, and on the ends of the sensory fibres of the vagus in the lungs.

13. The temperature of the body sinks under the influence of alcohol.

14. The reflex movements produced by irritating the skin in beheaded frogs are first increased under alcohol, and then diminished.

15. The excitability of motor and sensory nerves is at first increased and then lowered.

16. The power of muscular contraction is affected in the same way.

17. The quantity of chyle from the thoracic duct is at first increased, and then diminished.

18. The same is true with regard to the secretion of the gastric juice.

19. The quantity of urine increases, even though the peristaltic movements of the ureters follow each other at increased intervals.

20. The secretion of saliva from the submaxillary gland is increased, whether the alcohol be injected directly into the stomach or into the blood.

21. The action of ethyl-alcohol on the nervous system is direct, but is not caused by changes of the blood or of the circulation.

22. Methyl-, propyl-, butyl-, and amyl-alcohols, act similarly to ethyl-alcohol, but differ from each other in the intensity of their action. This difference in the intensity of the action of monatomic

saturated alcohols stands in intimate relation to the difference in composition in these compounds. Corresponding to this, methyl-alcohol acts less intensely than ethyl-alcohol, whilst propyl-, butyl-, and amyl-alcohols act in the ascending scale much more strongly.

WILLIAM STIRLING, D.Sc., M.B.

CHARCOT AND OTHERS ON AUDITORY VERTIGO (MÉNIÈRE'S DISEASE).

(Continued from page 240.)

We now come to speak of the nature of the ear-disease. We have assumed that the labyrinth is affected, but how it may be affected is yet to be considered. It may suffer primarily or secondarily. There may doubtless occur hæmorrhages in it just as these occur in the retina. Knapp strongly urges that aural diseases should be studied in close connection with eye diseases. If we find suddenly occurring nervous deafness, with or without other symptoms of Ménière's disease, there is certainly a possibility of hæmorrhage in the labyrinth, and we should enquire into the state of the heart, arteries, and urine, to see if there be a condition for hæmorrhage, as we should certainly do if we saw hæmorrhages in the retina. Saying nothing further of pathological changes occurring in the labyrinth itself, we speak of other aural conditions which interfere indirectly with it. As the following quotation from the Reporter's paper already referred to (see *Medical Times and Gazette*, August 17, 1872, p. 169) is only a compilation, it may be given here, with additions, as a summary.

'Even if it be granted that the semicircular canals are the parts in fault in Ménière's disease, they may be only secondarily so; they may be, indeed, only suffering from some fault in the more external parts of the aural apparatus. Increased pressure (resulting from stoppage of the meatus by wax, by catarrh, acute or subacute, and purulent processes in the cavity of the tympanum), "transferred from the stapes to the vestibulum, must necessarily place the semicircular canals in an abnormal state of pathological irritation"—(Trötsch, op. cit.) In other words, the primary changes may be in the non-nervous part of the ear. In syringing an ear in which there is a hole in the membrana tympani, we have symptoms essentially like those of Ménière's disease. Dr. Gowers has recently pointed out that Bell's paralysis of the face sometimes comes on with vertigo; considering the relations of the portio dura nerve to the ear, this is an important observation. The Reporter suggests that the vertigo may be caused by sudden paralysis of the stapedius, a muscle supplied by the portio dura nerve, and thus be owing directly to non-antagonised action of the tensor tympani. It is only in suddenly occurring cases that we can suppose symptoms of Ménière's disease to depend on primary changes in the labyrinth itself. Politzer (quoted and indorsed by Trötsch, op. cit.) says, "If a person who has formerly heard well becomes suddenly deaf, or hard of hearing, with the symptoms of an apoplectic attack, and there is at the same time an uncertain and staggering gait, but there are no symptoms of paralysis in other nerve-tracts, and if the examination shows a normal membrana tympani and perfectly permeable Eustachian tube, we may believe, with great probability, that there is an affection of the labyrinth."—(Trötsch, op. cit., p. 507.)

We now come to speak of the rare example of Ménière's disease recorded by Charcot. His patient was a woman fifty-one years of age. The vertigo was continual, and very strongly marked. It was present night and day, when lying down as well as when standing up, although in the latter position it was enormously exaggerated, as also when her bed was moved. But occasionally there were seemingly spontaneous aggravations. The following quotation gives a vivid account of her condition. 'Sometimes in the midst of apparent calm the patient, as you will no doubt see, is all at once seized with a violent jump. If you ask her the cause of this brusque movement, she invariably replies that she has had an attack. And in fact there are in this patient, besides the vertiginous state which I have tried to describe to you, paroxysmal exacerbations of vertigo, which constitute a kind of attack. They seem to be chiefly characterised by the sensation of a brusque movement of translation, not of surrounding objects, but of the patient herself; a movement entirely subjective, and of which this jumping is the only outward sign. Consciousness is unaffected, and when the attack is over, the patient can describe what she has felt. Sometimes, and most often, it seems to her that she falls headlong forward, at other times the fall seems backward. Lastly, this is the most rare, there is the sensation of rapid rotation of the body round its vertical axis, this rotation being always from left to right. Whichever it be, the motory hallucination is always followed by great anxiety, pallor of the face, and cold sweats. Finally, nausea and sometimes vomiting ends the attack, after which the vertigo subsides, so to speak, to its normal state.' The patient always has a whistling in her ears, but occasionally this is acutely increased. This exacerbation of the noise is a warning to her that an attack of vertigo is coming on, and that the jumpings are imminent.

For a long time the patient had had discharge from the two ears of pus mixed with blood. The right membrana tympani was thickened, the left was replaced by granulations, and on this side the hearing was considerably enfeebled.

Another remarkable feature was that the vertiginous state had been so severe and continued that for six years the patient had been obliged to keep her bed; before that time she had at intervals attacks but little marked; they became gradually more marked and nearer together until the vertigo and noises were, as stated, permanent, but occasionally exacerbated. It is mentioned that the patient has had attacks of hysterical convulsions, which, however, were independent of the attacks of auditory vertigo. At present the hysteria is only represented by incomplete left hemi-anæsthesia with ovaralgia of the same side.

We conclude this article by a reproduction of Charcot's remarks on it.

'In the first place, I shall show the intimate relation which exists between the sudden development of noises in the ear, or the rapid aggravation of these noises and the outset of vertiginous sensations. In reality, one of the special characteristics of Ménière's vertigo is that it is always ushered in and accompanied by the noises in question. Doubtless the singing, buzzing, and whistling of the ear are very common phenomena, and accompany different kinds of vertigo besides that which is a symptom of Ménière's disease, but in this affection they acquire at the time of the attack a predominance and intensity which is certainly not found in other diseases.

As patients say, the noise is harsh "like the whistle of an engine," or like the noise which will be made by "shaking violently a sack filled with nails." Again, it is compared to "the firing of guns or of fireworks." This noise is either exclusively or specially in one ear. In slight or recent cases it ceases with the attack of vertigo. But sooner or later, if the case be a grave one, it becomes persistent, continuing in the intervals in a milder form of singing and buzzing more or less annoying. Also the affected ear soon shows signs of more or less pronounced and permanent deafness.

After remarking in detail on the nature of the affection of hearing in different cases, Charcot says that there is reason to think, moreover, from the facts as a whole, that any pressure whatever exerted on the tympanum and propagated to the labyrinth by the chain of ossicles is sufficient to produce the symptoms of Ménière's vertigo.

'Considered, however, simply in the character of vertigo, it has some special characters. It is most frequently, if I may judge by the ten or twelve cases of my own, the sensation of a movement of translation of the entire body from behind forward, or from before backward, in a manner to give the patient an idea of a fall forward or backward as the case may be; again when there is added the sensation of moving round a transverse axis, an actual somersault, even a "saut de tremplin." Sometimes the body seems to rotate round a vertical axis either from left to right or from right to left. There are patients who in their different attacks think they have sometimes one sometimes the other of these modes of rotation. Remark that generally these movements are entirely subjective, real hallucinations, which only show themselves externally by a start, a movement of surprise, sometimes by the necessity the patient feels of clutching surrounding objects or sitting down. But it may happen that a fall actually takes place, and that the patient is violently thrown to the ground in the sense corresponding to the vertiginous sensation. I may cite, as an instance of this, the case of a lady, who in her attacks always felt thrown headforward, and who, in fact, in one of them, fell heavily on her face and broke the bone of her nose. I do not deny that the feeling of rotation or of moving is observed in vertigoes of the most varying kinds; but I believe I may say that they are not found in any so decided or so constant as in the vertigo of Ménière.

'It is important to observe that during the attack, whatever may be its intensity, the patient preserves absolutely perfect consciousness of his acts, and that when the first effects of the seizure are passed he can immediately, without any confusion, give an exact and detailed account of all he has experienced.

'Under the title of accessory phenomena I shall describe what follows. Almost always, nausea and vomiting mark the end of the attack. While the latter continues the face is pale, the skin cold and covered with perspiration, so as to produce an appearance of syncope rather than of "coup de sang." There may exist a transitory headache, more or less severe. There is never any embarrassment of speech or muscular spasm either of the face or limbs; never any tingling or numbness; no sensations whatever suggestive of aura; never any paralysis nor temporary paresis. At first, that is to say, when the disease of Ménière is yet but beginning, the vertigo appears under the form of distinct crises of short duration, separated by intervals of absolute calm,

during which the symptoms of the local disease from which they arise continue alone. But in the natural course of things, as the affection progresses, the crises tend to approach and to be confounded with each other, so as in the end to constitute a permanent vertiginous state, so to speak, in the midst of which occur paroxysms more or less frequent, and which reproduce all the phenomena of the old attacks. The patient I have shown you offers a very decided example of the subintransient crises which are usually observed, I repeat, in patients who have for years been the subjects of the grave forms of Ménière's disease.

'You will easily understand, gentlemen, the use which may be made of all the elements which I have been bringing together in the interests of diagnosis. . . . I reserve for another occasion what is known most positively relative to the pathological anatomy and theory. In what concerns the latter, the experiments of Flourens, of MM. Brown-Séquard, Vulpian, Cermak, Gall, Lœwenberg, which consist in producing in animals various lesions of the semicircular canals have furnished, we do not forget, important results. To-day, I shall conclude by a few words with regard to prognosis and therapeutics.

'It is very remarkable that, as a rule, the grave lesions of the nervous centres, which are so frequently the consequence of different diseases of the internal ear, do not usually occur in Ménière's disease, even when the latter has attained its highest degree of severity. The course of things in the most decided cases is this. The deafness gradually increases, till at a certain moment it becomes complete, absolute.

'The vertiginous symptoms and the whistlings go on, so to speak, at an equal pace, *i.e.*, they gradually decrease and finally disappear. They did so, for example, in the case of the patient of whom I have spoken above, and who in one of his attacks fell on the Place de la Bourse. Subject to the whistlings and vertigo since 1863, he now finds himself quite free from them. But, on the other hand, he is now deaf, so deaf that though he lives close to the Champ-de-Mars he heard absolutely nothing of the explosions of powder in the Avenue Rapp (1871). I am often asked if it would not be well to seek the means by some intersection, of hastening the denouement, at least in grave cases when, for instance, the patients are reduced by it to the lamentable state you have seen in the patient Gir—. It is a point which I offer for your consideration.

'Whatever it be, I must not conceal from you that Ménière's disease often resists the best-directed treatment. I have, however, several times seen vertigo occurring with catarrh of the tympanum decrease, and even disappear, under the influence of the common treatment of the latter affection.

'Here I may remind you of the very interesting case observed by M. Hillairet in which vertigo completely ceased after the opening of an abscess in the middle ear. The application of energetic revulsives must not be neglected in the severe cases. *Apropos* of these, I will describe a case I saw lately. One of our brethren in the provinces, now forty-four years of age, felt, for the first time six years ago, some heaviness of the head and buzzing of the ears returning in paroxysms. Some months later, while driving in the country alone, he all at once felt insupportable whistling in the left ear, and at the same time his head becoming heavy seemed to drag him forward. He was obliged to get out of his carriage, and to lie down for an instant upon the road. Nausea, followed

by vomiting of glairy matter mixed with bile, ended the attack. Attacks of the same kind have frequently occurred since, and in the meantime the hearing of the ear affected has become feebler. Examination discovers nothing on this side except a certain degree of thickness of the membrane of the tympanum. All treatment tried having failed, I proposed the application of "pointes de feu" on the left mastoidal region. The applications were repeated three or four times. After this treatment all the symptoms were obviously diminished.'

J. HUGHLINGS JACKSON, M.D.

RIZZOLI ON A CASE OF TRANSCRANIAL ARTERIO-VEINOS ANEURISM.*

After rapidly passing in review all that has been written on the subject of the aneurisms of the arteries of the head from the time of Morgagni to the present day, and pointing out the possible utility of auscultation in the diagnosis of intracranial aneurism, Dr. Rizzoli relates the following case.

The subject was a girl who, for the first eight years of her life, had not suffered from any disease of importance, nor, so far as her parents were aware, had ever fallen or received a blow on the head. When she was eight years old, in September, 1872, she was for some hours in the open air with her head uncovered, exposed to the burning rays of the sun. When she returned home in the evening, she felt giddy; a little later she complained of severe pain in the head, which was soon followed by repeated vomiting, and by convulsions in which she fell to the ground in a state of complete unconsciousness. She remained in this state for some days, but gradually recovered, and was apparently as well as before. At the end of a fortnight, however, a similar attack occurred; this subsided, and was followed by others at intervals of fifteen or twenty days. It was not until three months after the first attack, that the mother accidentally observed a small tumour in the occipital region of the little patient. The tumour went on increasing, but the parents did not take particular notice of it; and it was not until April 23, 1873, after a very severe paroxysm in which they feared that she would die, that they brought her to the hospital in Bologna, and placed her under the care of Professor Rizzoli.

On admission, she was found to be well developed for her age, intelligent, and docile. The head was rather large; the skull was thin (as was ascertained by percussion); the parietal and frontal protuberances were well developed, especially the former. A tape carried over the head, from the apex of the glabella to the junction with the spine, measured $14\frac{1}{2}$ inches; and from one mastoid process to the other $15\frac{3}{4}$ inches. The circumference of the skull was $21\frac{1}{4}$ inches. The left pupil was a little more dilated than the right. There was slight convergent squint of the left eye. The lips were directed rather obliquely from left to right, and from below upwards, chiefly in laughing and speaking. The tongue was movable in all directions, but deviated somewhat to the left. Sensation was more perfect in the right limbs than in the left. The muscles of the left side were less developed and weaker than those of the right. In walking at an ordinary pace, she crossed the legs a little, turning the foot in-

wards; but this was not observed when she walked quickly.

In the occipital region, below the lambdoid suture, was seen a pulsatory semi-elliptical tumour, having the convexity directed upwards, and the two extremities downwards. Commencing two finger-breadths to the left of the middle line, it reached on the right nearly as far as the mastoid process, being about $3\frac{3}{5}$ inches long, and $1\frac{1}{2}$ inches broad at its widest part. The skin over it was sound, and well covered with hair. The pulsations of the tumour were visible to the naked eye, especially at its most prominent part. On applying the finger to it, a thrill was felt, like that perceived in cases of cirsioid aneurism. On applying pressure, this thrill diminished; and it disappeared entirely if the pressure were increased.

By direct or mediate auscultation, there was perceived in the middle (most prominent) part of the tumour a rather strong expansive bruit, diminishing in intensity as the ear was carried more forward. This murmur was isochronous with the beating of the heart and the pulse in the large arteries; it almost always ceased, and the size of the tumour was diminished, when the left carotid artery was compressed; no change was produced by compressing the right common carotid, even strongly; and sometimes a scarcely perceptible murmur remained when the left common carotid was compressed. On applying pressure simultaneously to both carotids, all bruit ceased; when the pressure was removed from the left carotid the tumour again swelled up and pulsated, and the blowing sound was again heard in it and in the interior of the skull. In the part corresponding to the tumour, on the right and left, the occipital bone was notably hollowed inward, while in the centre, a little towards the right, was a nearly circular hole about $0\cdot68$ inches in diameter. No change was produced in the tumour by coughing, or by deglutition or respiration. On firmly pressing it, no pain was felt.

From these signs, Rizzoli diagnosed an aneurism passing through the occiput and communicating with the interior of the cranium, and covered externally by cirsioid dilations of the occipital artery. Professors Brugnoli, Taruffi, Vella, and Verardini, agreed in this diagnosis. To attain greater certainty, however, a steel pin was introduced; the point entered a cavity in which it could move freely in all directions, and its removal was followed by the escape of a few drops of blood. Subsequently, the cannula of a Pravaz's syringe was introduced into the cavity, when a little arterial blood was found to escape.

The signs already described indicated that the tumour was an aneurism of a branch of the left carotid artery. The fact that cerebral symptoms had been present before the child's mother had noticed the tumour, led to the supposition that the meningeal branch was affected, and that the aneurism in its growth had produced erosion of the bone from within outwards. This idea was supported by the fact that Begin and Krimer had in two analogous cases found the bone perforated by the tumour, and that Giraudet admitted the probability of erosion of the bone in similar cases.

But, on making a more careful examination, Rizzoli found that, when he made pressure a little to the right of and below the above-mentioned hole, on a rather large serpentine arterial twig, all pulsation and bruit ceased both in the aneurism and in the

* *Memorie dell' Accademia delle Scienze di Bologna*, serie iii. tomo iv. The present article is taken from an abstract in the *Gazzetta delle Cliniche* for February 10 and 24.

cranium, the tumour at the same time becoming empty. Here, then, was the arterial branch from which the aneurism sprang; but it lay to the right, and the pulsations of the tumour were arrested by compressing the left carotid artery. Remembering, however, that arterial ramifications, when they become cirroid, spread extensively, Rizzoli was of opinion that the aneurism arose from a branch of the left occipital artery, which reached beyond the middle line.

The fact that the aneurismal bruit could be heard within the cranium might be explained, not only by the thinness of the walls, but perhaps by the aneurism being in communication with an intracranial venous sinus. As, however, the tumour had not the special characters of an arterio-venous aneurism (according to Holmes, a continuous soft murmur, interrupted by an intermittent arterial sibilus) Rizzoli refrained from expressing an absolute opinion.

The symptoms of paralysis and other morbid phenomena which had attacked the child, and had increased so much as to threaten her life, were apparently independent of the aneurism, as they appeared before the tumour was discovered, and no inconvenience was produced by compressing it.

On May 9, the patient had nausea, with attempts at vomiting, pains in the head, and weakness. These symptoms passed off in the evening, but returned in greater force the next day, and were accompanied with paleness of the face and restlessness; the aneurism pulsed more strongly than usual. This condition continued on the 11th, and on the morning of the 12th she felt well enough to rise from bed, but was immediately obliged to return. She complained of a tingling sensation in the left limbs. In the evening there was fever, with a temperature of 103.28 ; pulse strong, 100. The febrile state continued on the 13th, and on the 14th there were general tremor, inability to seize or hold anything with the hand, and very severe pain in the head. On the 15th she had a severe paroxysm of convulsions; the eyes were open and turned to the right, the pupils dilated, the head erect, the limbs bent, the pulse frequent, small, and intermittent. She did not answer questions, and did not feel the prick of a pin. A few minutes after the attack had passed off, she was covered with a profuse sweat, and appeared stupefied. On the 17th she had two convulsive attacks, with an interval of six hours, the second being very violent; and the convulsions again occurred on the next day. On the 19th there was total loss of vision, with extreme dilatation of the pupils and convergent squint. Left hemiplegia, meteorism, and retention of urine followed, and she died in three days.

At the necropsy, which was made by Professor Taruffi, the lateral ventricles were found much dilated, and filled with a transparent fluid. The walls of the right lateral ventricle were softened and diffuent anteriorly. The anterior part of the right optic thalamus was softened, as was also the right cornu Ammonis. Neither on nor in the softened parts were there any hæmorrhagic points, such as generally accompany cerebral softening. In the right lobe of the cerebellum, the meninges were closely adherent to the brain-substance over a large circular tract; the surface was slightly raised with ecchymoses. This portion of the cerebellar substance, having about the size of a small hen's egg, was very resistant under the knife; under the microscope it was found to be formed of bundles of nerve-fibres, and had the appearance of a neuroma. On

the internal surface of the occipital bone, the left arm of the osseous cross was lower than the right; and to the right of the point of union of the ascending with the left branch, was an aperture passing through the entire thickness of the skull; it was nearly circular, having a diameter of 0.27 inch within, and 0.68 inch externally. By this aperture, the cavity of the aneurism communicated with the interior of the skull. To the left of the crucial eminence, below the origin of the transverse arm on this side, was a small lacuna in the bone, with a nearly circular border about 0.12 inch in diameter. The two transverse sinuses of the dura mater, the right of which was larger and lay higher than the left, were perforated at their origin; the left, which presented the smaller aperture, opened into the lacuna, and the right into the aneurismal sac. On tracing the occipital arteries, it was found that the left, in place of diminishing, became gradually larger and tortuous, especially opposite the external occipital protuberance, and that a large tortuous branch proceeded to the right, anastomosing with small ramifications of the right occipital artery. This branch opened beneath the pericranium into the above-mentioned aperture, the pericranium forming the outer wall of the aneurismal sac, while the inner was formed by the bone around the aperture and by the right transverse sinus, with which the aneurism communicated through the aperture.

From this it results:—1. That the profound and various lesions found in the cerebrum and cerebellum were the cause of the symptoms and of death; 2. That the diagnosis of the aneurism was in all respects correct.

Professor Rizzoli discusses the question whether the aperture in the occipital bone was formed from within, by the pressure of the blood escaping from the transverse sinus after its perforation, or from without, by the pressure of the aneurism. The first hypothesis was favoured by the study of other tumours containing blood and communicating with the sinuses, which may be produced in various modes. Taking into consideration the known facts, and the existence of the small lacuna in connection with the left transverse sinus, there would seem no doubt that the erosions were produced by the blood in the sinuses.

On the other hand, the greater diameter of the aperture externally than internally, and the presence of a depression on the outer surface of the occipital bone, produced by the cirroid branches of the occipital artery, indicated that the erosion commenced from within, and was completed from without by the cirroid vessels and by the aneurism.

He remarks that, had there not been in this case indications of incurable cerebral disease independent of the aneurism, he might have hoped to treat the latter successfully. Hodgson refers to cases of intracranial aneurism, in which spontaneous cure took place; and Consolini successfully treated a circumscribed traumatic aneurism of the meningeal artery by digital compression of the carotid. Cases of cure of aneurism and wound of the occipital artery are also known.

Having briefly noticed some cases of cure of aneurism of the occipital artery, Professor Rizzoli gives the history of a case which came under his notice towards the end of 1870. The patient, named Cesare Braggia, received a rather deep wound in the left mastoid region, by being struck with a knife from behind; the wound was directed obliquely from above downwards towards the first cervical arteries; there was

much hæmorrhage, which was nearly arrested. He was taken to the hospital, where Dr. Barbieri applied adhesive plaster and a compress over the wound, thus entirely arresting the bleeding. The patient returned home, where he was under the care of Dr. N. Vecchi. On removing the dressing on the third day, the wound was found completely cicatrised, and a large patch of ecchymosis extended along the posterior margin of the sterno-cleido-mastoid muscle. The next day there was perceived under the cicatrix, a roundish prominence as large as a small nut, which pulsated isochronously with the radial artery. Dr. Vecchi then sent the patient into hospital, under the care of Dr. Rizzoli. On examination, the latter found the tumour above described, lying behind the base of the mastoid process, and pulsating visibly to the naked eye. A thrill was perceived on palpation, and a prolonged and expansive blowing murmur on auscultation: the pulsation and bruit ceased, and the tumour diminished, on compressing the left carotid artery at its bifurcation. This did not occur when the vertebral artery was compressed. The diagnosis was, circumscribed traumatic aneurism of the left occipital artery. After direct pressure on the artery by means of a linen compress and a bandage had been kept up for twenty-four hours, the left common carotid being also compressed with the finger at intervals during the same time, the tumour was found to be smaller, hard, and scarcely pulsating. By continuing this treatment for five subsequent days, a complete cure was produced.

The author finally refers to two cases of wound of the occipital artery treated successfully. In the first, there was a lacerated and contused wound in the occipital region, with profuse external hæmorrhage; this was stopped at the time by strong direct compression, but returned several times, and was finally arrested by acupressure. In the second case also, the hæmorrhage was arrested by acupressure. Both patients completely recovered. A. HENRY, M.D.

FORENSIC OPHTHALMOLOGY.

ON INJURIES OF THE EYE IN THEIR MEDICO-LEGAL RELATIONS. BY PROFESSOR ARLT, OF VIENNA.*

(Continued from page 242.)

7. *Laceration of the Iris* as a result of contusion of the globe generally occurs at the ciliary border; it may be so slight as to be scarcely perceptible, or there may be total separation of the ciliary body. The iris is rarely lacerated at the same time in a radiating direction (from the pupil to the ciliary border), and still more rarely is the blood in the chamber traced to small fissures confined to the pupillary edge, or to clefts between the radiating fibres of the iris.

After partial separation of the ciliary border (iridodialysis) the sphincter meets with no resistance from the radiating fibres at the injured part; and the pupil assumes a form which may be simply described as kidney-shaped. This deformity is sometimes the only sign that slight separation has taken place. If the aperture of the iris be not too small, ophthalmoscopic examination discovers a

refraction of red light from the fundus of the eye, if the media be transparent. More extensive separations manifest themselves by the formation of an aperture at the periphery (a second pupil). When there are large apertures having this origin, the natural pupil may be reduced to a small cleft or altogether obstructed.

After total or nearly total separation, the iris contracts into a small ashy grey membrane.

Radiating lacerations produce a true coloboma; the one or the other limb of the separated iris may be drawn against a laceration in the sclerotic, or may lie on the capsule in the neighbourhood of the natural pupil, and become adherent to it through inflammation. I have seen a case where, in consequence of a blow on the globe in the neighbourhood of the insertion of the right inferior rectus, the iris was separated in its upper third from the ciliary process, and at the same time divided perpendicularly from the middle of the separated ciliary border to the pupil.

Prognosis.—Laceration of the iris is of importance in relation to vision only when the natural pupil is much dilated, or when a second pupil is formed, and is so large and so situated as to give rise to double vision with the one eye. There may also be more or less extensive deformity. Extensive iritis is not caused.

Treatment.—This inquiry does not call for any special treatment beyond rest and protection of the eye, and cold applications at first. The blood will be removed slowly; yet the advice to use spirit lotion with tincture of arnica is not to be altogether set aside. It is unnecessary to open the chamber to remove the blood in simple hæmophthalmus anterior; it is only when there are signs of hæmophthalmus posterior (impaired perception of light and increased tension), and absorption is slow, that the blood may be carefully and slowly evacuated from the chamber.

8. *Bursting of the Choroid.*—Frequently only one vessel is affected, and the effusion is limited to the parenchyma of the choroid; or the blood is effused between the sclerotic and the choroid (in large quantity only after injuries in which the globe is at the same time laid open); or it presses on the affected part of the choroid, and breaks through it into the vitreous body. In a higher degree of bursting, there is seen to be laceration of the choroid to a greater or less extent in several parts.

Diagnosis and Prognosis.—More or less numerous and extensive effusions of blood in the tissue of the choroid have been observed after contusions of the globe, but without evident change; in themselves, they do not interfere with vision. Reactive inflammation, however, may set in, and the retina may become implicated. The effusions can only be discovered by the ophthalmoscope, and appear as red spots or points. In many cases (and this occurs, according to Berlin, also in small subchoroidal extravasations) the part of the retina lying in front is clouded, but becomes clear in a few days.

Bursting of the vessels of the choroid is of more serious importance when it leads to displacement or laceration of the superjacent portion of retina. If these changes take place in the neighbourhood of the macula lutea, the patient complains of interference with vision; when situated more towards the periphery, with effusion of blood in the vitreous body, they can only be made out by ophthalmoscopic examination of the field of vision. At first, the evi-

* *Wiener Medizinische Wochenschrift*, April 4 and 11, 1874.

dence of injury may be observed by blood in the vitreous or in the aqueous humour. At a later period, the raising or perforation of the retina becomes apparent; but it may still be more or less masked by consecutive obscuration of the vitreous body.

Laceration of the retina of this kind may heal in such a way, that the cicatrix can scarcely be discerned, and no perceptible functional disturbance remains. Even the portions of retina that had been raised may become functionally competent after the absorption of the blood. If, however, inflammation set in, the function of the part may again be more or less impaired through contraction of the cicatrix. Cases of this injury should, therefore, be kept under observation for several, often for many, months.

9. *Lacerations of the Choroid* are chiefly observed in the neighbourhood of the posterior pole, on the temporal side of the optic disc, and, in special circumstances, on the nasal side. The manner in which they are produced has been already explained in section I.

Diagnosis.—At first the cleft is covered in with blood, part of which lies in it, and part escapes into the vitreous body and may even reach the anterior chamber. After clearing of the media, the rents in the choroid are seen at first yellow, afterwards clear white, the light being reflected only from the denuded sclerotic. The edges of the clefts appear for some time red, and at a later period are often strongly pigmented. Over the clefts, the vascular networks are observed to run unchanged, except when they have been torn through by the injury. Along with this, there may be the signs of reactive inflammation in the immediate neighbourhood, perhaps also partial raising of the retina. At a later period, threads of connective tissue often run through the vitreous body in front of the rent, or in its immediate neighbourhood, and allow the rent to be only imperfectly seen.

A laceration of the choroid in the equatorial region or in front of it must be expected, if the globe be struck by a blunt instrument in this region. Hitherto, posterior laceration of the choroid on the nasal side of the optic papilla has been observed only as the result of the impact of a foreign body on the nasal side of the sclerotic. A posterior choroidal laceration on the temporal side of the optic nerve does not exclude an anterior laceration on the same side, if the globe have been pressed towards this side.

In a case related by Stellwag, a blow from a piece of iron on the inner part of the right eye was followed by a double rent of the choroid on the inner side of the entrance of the optic nerve; one portion was as long as two or three diameters of the papilla, and was vertical, while the other, about one diameter in length, ran horizontally, forming a nearly right angle with the upper end of the other. In some parts, irregular laceration of the retina could be seen through the choroidal laceration. Beyond the outer edge of the rent, as far forwards as the ora serrata, the retina was raised in the form of a furrowed vesicle. The vitreous body was slightly obscured. Acuteness of vision was impaired, and there was considerable limitation of the outer circumference of the field of vision.

In a case recorded by Aub as having occurred in Knapp's practice, the left eye of a boy aged fourteen was struck by a piece of wood on the temporal side. Fourteen days afterwards, after full dilatation of the pupil, a hole, running upwards and backwards,

with pigmented edges, was seen at the anterior and outer part of the fundus oculi, at the union between the choroid proper and the ciliary portion. After the absorption of blood which had been effused into the vitreous body, an isolated rupture, having two prolongations upward and three downwards, was seen in the neighbourhood of the macula. At this time the anterior rupture was cicatrising, but its edges were still pigmented.

Knapp figures and describes an eye which was injured a year previously by the discharge of a pistol loaded only with powder. Numerous grains of powder were found in the cornea and sclerotic. The patient could count fingers at the distance of only a foot; the field of vision at the nasal side was much narrowed. With the ophthalmoscope movable opacities, somewhat obscuring the fundus oculi, were observed in the vitreous body. The lower and outer side of the entrance of the optic nerve was environed by a curved white streak; and in the most anterior part of the fundus, also at the lower and outer part, were numerous irregular white spots, which were readily recognised as defects in the choroid, exposing the sclerotic. The larger choroidal and the retinal vessels could be seen entire: at one part, however, the retina was slightly raised in the form of an oval bluish vesicle.

In these three cases, the posterior laceration of the choroid was in the meridian in which the violence was applied to the globe in front. They are opposed to the idea of the laceration being caused by *contre-coup*.

Prognosis and Treatment.—The traumatic reaction may be severe; but on the whole it is slight. The treatment is coincident with that of posterior hæmophthalmus. At a later period, especially when retinitis sets in, it will be necessary to protect from light and to restrain the accommodative function of the other eye; and to regulate the patient's diet.

In most cases, vision is limited to quantitative perception of sight. In some cases, this may be only first discovered after a week or two: cases where vision becomes again nearly or quite as complete as formerly, are exceptional. At the point of rupture, an opaque spot often remains: in some cases, the field of vision becomes more or less limited. This is produced more rarely by laceration of the optic fibres than by reactive inflammation with or without consecutive raising of the retina (through cicatricial contraction). The function of the eye may also be permanently impaired by the formation of connective tissue in the vitreous body.

10. *Concussion of the Crystalline Lens* in consequence of violent blows, &c., or of concussion of the cranium (or of the whole body), very rarely produces bursting of the anterior capsule, except in those cases where the lens is thrown against a rent in the sclerotic. Knapp has observed laceration of the posterior capsule after a blow on the eye; and Aub observed this injury in the case of posterior and anterior laceration of the choroid, described above.

Much more frequent is partial or total stretching or laceration of the zonule of Zinn. Whether concussion of the eye, without either bursting of the capsule or laceration of the zonule, directly produces opacity of the lens, is not determined with certainty; but it is usually assumed that it does so. The fact that Berlin produced opacity of the anterior cortical substance in a cat's eye by a blow with an elastic rod, tends to show that cataract may be a direct result of contusion of the eye.

When unilateral cataract appears sooner or later after an injury in which the eye has suffered contusion, the cataract may occur without lesion of the capsule and zonule, and in consequence of the bursting of the choroid produced by the injury: that is to say, mediately through hæmorrhage and its sequelæ, through reactive choroiditis and retinitis, and through consecutive raising of the retina. It has long been known that, in cases of cataract following contusion, which perhaps the patient only remembers after questioning, there is very often amaurosis or amblyopia, which can only be attributed to injury of the choroid and retina (through the contusion, perhaps also through the penetration of a small foreign body which has escaped detection), and the causal connection between cataract and inflammatory lesions of the choroid, and especially between cataract and raising of the retina, has been determined with certainty in recent times. In a large number of these cases of unilateral cataract, after the history of an injury has been traced out, this mediate production of cataract may be suspected if there be a certain discoloration of the iris, although the fibres remain, and if the pupil be partially or entirely dilated. Synchysis of the vitreous body, when the lens is not displaced, indicates still more distinctly the mediate origin of the cataract. Cataracts following raising of the retina are attended with posterior synechiæ, which are generally unnoticed, being unaccompanied by any remarkable redness of the cornea or by pain. These synechiæ must not be confounded with irregular pigmentary groups in the anterior capsule, which (since Beer) have been found after many injuries, attended with concussion of the globe.

In determining the causal connection in special cases, not only must the globe be examined by palpation, but it is essential to examine the perception of light and the extent of the field of vision. In cataract produced directly and simply through concussion of the lens, the optic structures beyond may remain normal.

(To be continued.)

ANATOMY AND PHYSIOLOGY.

KOWALEWSKY ON THE MOVEMENTS OF THE BILE.—Professor W. Kowalewsky communicated to the fourth meeting of Russian *savants*, held at Kasan, in 1873 (Pflüger's *Archiv*, vol. viii. part II—12), the results of his researches on the doctrine of the mechanics of the movement of the bile. The experiments were performed on curarised cats. He found that: 1. The motive power for the bile is not constant, either in different animals, or in one and the same animal at different times; e.g. the pressure in curarised cats varied from 12 to 20 millimètres of mercury. The different animals showed variations at different times: 12.4—14.1, or 17.5—18.3, or 19—20 millimètres of mercury. 2. These last cited variations depend upon the blood-pressure in the large arteries; such increase of arterial blood-pressure being followed by an increase of the pressure of the bile. A certain time, however, generally elapses before increase of the arterial blood-pressure is followed by a corresponding change in the bile-pressure (estimated by the manometer); the latter is also not the immediate consequence of the former, but depends upon the change in the secretion, or on the

absorption from the bile-passages. 3. The greatness of the resistance to the outflow of the bile into the intestine also varies, even in one and the same animal, in curarised cats. 4. On comparing the greatness of the motive power with the resistance, it is at once observed that a cessation of the secretion of bile, or a retrograde suction under physiological conditions, cannot occur, but a stand-still of the outflow of the bile into the intestine may occur, until the pressure on the walls of the gall-ducts has reached the height of $3\frac{1}{2}$ to $7\frac{1}{2}$ millimètres of mercury. From this moment the bile must flow in drops into the intestine. This latter must occur oftener in fasting animals, for in them the gall-bladder is generally tensely filled. Thereby can be explained the great difference which exists between the bile from the gall-bladder of fasting animals and the freshly secreted liver bile, for with a tensely filled gall-bladder the continually secreted bile must flow into the intestine without previously going into the gall-bladder.

WILLIAM STIRLING, D.Sc., M.B.

BOGOLJUBOW ON THE GASOMETRIC ANALYSIS OF BILE.—Dr. W. Bogoljubow (Inaugural Dissertation, Kasan, 1873) has made comparative gasometric analyses of bile, and found that the quantity of chemically united carbonic acid in the bile from the gall-bladder of fasting animals is almost none, and the quantity of free carbonic acid may fall to two volumes per cent., whilst the fresh bile from the liver, secreted at the same time, contains 64 per cent. of chemically united carbonic acid, and 7 per cent. in the free condition.

WILLIAM STIRLING, D.Sc., M.B.

TROITZKY ON THE EFFECT OF TEMPERATURE ON THE NERVE-CURRENT.—At the meeting of Russian *savants*, in Kasan, 1873 (Pflüger's *Archiv*, vol. viii.) A. Troitzky read a communication on the estimation of the rapidity of the propagation of stimulations in the nerves of the frog at different temperatures and with different intensities of the stimulating current. He has arrived at the following results. 1. With slightly stimulating intensity of the current, the rapidity of the propagation of stimulation in the nerve is at its maximum between 68° Fahr. and 50° Fahr. The rapidity diminishes when the nerve is heated to 86° Fahr., or cooled to 32° Fahr. 2. With stronger currents, the influence of temperature on the rapidity of propagation in the nerves diminishes. The rapidity is more influenced by the strength of the stimulating current than by the temperature. 3. With very strong currents, the influence of temperature disappears completely. 4. The greatness of the rapidity of propagation in nerves depends upon the strength of the stimulation, and stands in direct proportion to the same.

WILLIAM STIRLING, D.Sc., M.B.

NAUMOW AND BELJAEW ON THE EFFECTS OF OXYGEN ON TEMPERATURE AND CIRCULATION.—A. Naumow and S. Beljaew (Pflüger's *Archiv*, vol. viii.) have experimented on the temperature of the body and the rapidity of the blood-current under inspiration of oxygen and atmospheric air. Their experiments on man and dogs showed that the temperature during respiration of oxygen is exactly the same as when atmospheric air is breathed. The number of heart-beats is also uninfluenced by oxygen. The rapidity of the blood-current in the carotids seems, however, to increase under the influence of oxygen.

W. STIRLING, D.Sc., M.B.

NAWROCKY ON THE REFLEX SALIVARY SECRETIONS.—F. Nawrocky, of Warsaw, read a communication at the meeting of Russian *savants*, in Kasan, in 1873 (Pflüger's *Archiv*, vol. viii.), on the reflex salivary secretion. Within the last few months two papers (Owsjannikow and Tschirew, Grützner and Chlapowsky, abstract of both in *Journal of Anatomy and Physiology*, vol. viii. 183) on this subject have appeared, which add a new fact to the doctrine of the reflex secretion of the saliva: viz., occurrence of the salivary secretion on stimulation of the sciatic and auricular nerves. On repeating these experiments, Nawrocky and L. Rklicky obtained results which completely coincide with the prevailing doctrine of reflex salivary secretion, and show that such a secretion is only caused on stimulation of the lingual and glossopharyngeal nerves. When these authors, sometimes, in the case of dogs, observed the saliva to flow rapidly from the duct on stimulation of the sciatic nerve, this occurred only at the beginning, immediately after the stimulation, and in such quantity as warranted them in presuming that it was previously formed, and was pressed out of the gland through the increased blood-pressure. Afterwards, the outflow ceased entirely, or, in the case where salivation occurred already before the stimulation (which is not rare in dogs), the secretion was not more copious during than before the stimulation. W. STIRLING, D.Sc., M.B.

ARNSTEIN ON THE NERVES OF THE DIGESTIVE CANAL.—Professor C. Arnstein (of Kasan) communicated (*ibid.*) the results of Gonjaew's experiments made in his laboratory, on the nerves of the digestive canal.

1. Ganglion-cells occur in considerable quantities in the walls of the œsophagus of the frog.

2. The nerve-stems of the mucous membrane of the œsophagus of the frog lie generally in lymph-spaces. The fine nerve-fibres, devoid of the white substance of Schwann, which branch from these nerve stems, run within the *Saftcanäle* between the bundles of connective tissue.

3. A thick net of non-medullated nuclei containing nerve-fibres is distributed in the mucous membrane of the œsophagus of the frog. From this net, fine nerve-fibres branch off and ascend vertically in the direction of the epithelium, and can be followed to the interstices between the epithelial cells.

4. The nerve-fibres of the mucous membrane of the stomach and intestine of the frog arise from nerve-bundles, which often pierce the muscular coat in company with small arteries. In their further course, two principal directions are to be made out. Part of the fibres ascend vertically from the deeper layers of the mucous membrane and reach the epithelium of the mucous layer. In this course, they give fine threads to the gastric and intestinal glands. A connection between the nerve-threads and the epithelial structures could nowhere be made out. The other part of the nerve-fibres of the mucous membrane ascend at first in the form of an arch, and later have a direction parallel to the surface of the mucous membrane. In that the above named bendings occur at different heights, so that on a vertical section there appear three or four parallel rows of nerve-fibres. These nerve-fibres are destined for the capillary vessels of the mucous membrane, and form, on making sections parallel to the surface, long drawn out nets around the blood-vessels; single

nerve-threads touch, in a radiating manner, the walls of the capillaries. W. STIRLING, D.Sc., M.B.

KOWALEWSKY AND WYSSOTSKY ON AIR IN THE BLOOD-VESSELS.—Professor N. Kowalewsky and N. Wyssotsky (in Kasan), communicated (*ibid.*), the results of a series of experiments upon the physiological action of the injection of air into the blood-vessels. The experiments were made upon curarised dogs and cats, in whom artificial respiration was kept up. The air was introduced into the blood-vessels by means of a graduated syringe. The following are their results.

1. A very considerable quantity (200 cubic centimètres, and more in the dog) of air can be injected into the external jugular vein in the direction of the heart without disadvantage, when the injection is not completed at once, but only small quantities are introduced at a time.

2. Much smaller quantities (12 cubic centimètres for the cat, 14 or less for the dog) injected at once, are sufficient to kill the animal.

3. With each injection of a small quantity of air into the central end of the external jugular vein, sinking of the arterial blood-pressure, with acceleration of the heart's action occurred. Afterwards, the pressure rose above the normal; then followed a succession of wave-like variations of the blood-pressure with periodical retardation of the pulse (excitation of the vagus) on the height of each wave; lastly, return of the circulation to the normal. These phenomena point to a temporary difficulty in the passage of the blood from the venous into the arterial system (sinking of the blood-pressure), and to a disturbed exchange of gases in the blood (the consequent increase of pressure and the waves as the result of the stimulation of the vaso-motor centres). On dissecting an animal into which large quantities of air had been injected gradually, either none or very little air was found in the left side of the heart and arteries, but it was found in the right heart and in the pulmonary arteries, though the amount was much less than was injected.

4. If a considerable quantity of air be injected at once into the jugular vein, in the direction of the heart, then the arterial blood-pressure falls to the height of the pressure of the stationary column of blood, and death follows. The phenomena in the circulation resemble the effects of ligature of the vena cava inferior. Death follows, because the blood is prevented from passing from the veins into the arteries, in consequence of the formation of considerable quantities of froth in the right side of the heart. The cause of death is an arterial anæmia (notwithstanding that the action of the heart continues for some time).

5. Injection of about 12 cubic centimètres of air into the carotid towards the brain produces a marked increase of pressure in the arterial system, as an expression of the stimulation of the vaso-motor centre, in consequence of arterial anæmia. After a time the circulation returns to the normal, and a second injection of air, this time into the peripheral end of the carotid, may have the same phenomena as results. If the animal be dissected after such a repeated injection, air-bubbles are found in the vessels of the pia mater, in the venous sinus of the dura mater, in the right heart, and in the pulmonary artery; whilst in the left heart and in the great arteries of the systemic circulation, scarcely any air is to be found.

6. Experiments in which frothy (shaken with air)

defibrinated blood is injected through the pulmonary artery of the excised lungs, as well as the *post mortem* examinations of the experiments described in no. 5, show that the pulmonary and central capillaries do not present any unsurmountable resistance to the blood charged with air-bubbles. The hindrance to the blood-current in the capillaries is, if present at all, only temporary. Beyond that, we know from examination of the bodies of animals after the experiments made under 3 and 5, that the air, on its way through the lungs, may disappear from the blood-vessels (transpiration?). The danger of the entrance of air into the veins does not consist in the formation of capillary embola in the lungs or brain, but in the production of a considerable quantity of froth in the right heart, whereby a mechanical hindrance to the normal circulation and its consequences—anæmia of the aortic system—is produced.

WILLIAM STIRLING, D.Sc., M.B.

SKWORZOW ON THE HISTOLOGY OF THE HEART AND ITS COVERINGS.—Dr. J. Skworzow thus groups together (*ibid.*) the results of his researches on the histology of the heart and its coverings.

1. The heart, together with its pericardium, in mammalia, is richly provided with lymphatics. The ventricles, auricles, and the pericardium proper, each possesses its independent system. The lymphatics of the pericardium can be filled by puncture (*Einstich*), when the cannula is introduced between the serous and fibrous layers. This succeeds most easily in the heart of the calf.

2. Henle's intermuscular spaces (*Spalträume*) in the cardiac muscles, are lymph spaces, which empty themselves into the subserous lymphatics on the surface of the heart.

3. The proper serous layer of the exocardium and pericardium is very poor in lymphatics and blood-vessels; the greatest portion of these lies in the tissue which unites the serous with the underlying layers.

4. Vertical lymph-spaces (*Lymphträume*) penetrate through the serous layer, and unite the cavity of the pericardium with the subserous network of lymphatics.

5. The above described lymph-spaces do not permit the fine particles suspended in the injection-mass to pass in the direction of the cavity of the pericardium, but easily in the opposite direction (see the experiments of Schumkow described below).

6. The outer and inner surfaces of the heart, or more correctly the serous layers which cover these, are richly provided with sensory nerves, which, as it appears, end in the form of a net, immediately underneath the epithelium. These nets of nerve-fibres are provided with cell-like enlargements containing nuclei.

7. In the proper heart-muscles of mammals and of the frog, no ganglion-cells exist (this is contrary to Remak's statement).

8. The chief masses of ganglion-cells lie in mammals in the septum auricularum (similarly in the frog) and at the mouths of the arteries. Beyond these, a number of ganglion-cells are found in the fatty tissue of the sulci, especially in the transverse furrow.

9. Absorption from the pericardium, as well as from other serous cavities, is provided for by stomata, which lead into the lymphatics.

10. The formation of stomata is caused by a distinct tendency of the endothelial-cells to gradually

assume a curved and circular arrangement; the cells towards the centre become atrophied by pressure, and stomata are formed.

11. The completely formed stomata appear when treated with silver, as black specks, which lie in the centre of the radially arranged endothelium.

12. The endothelial cells of the cavity of the pericardium are very various in form and size, and show a great tendency to the proliferation of nuclei and cells. The endothelium appears to be a self-reproducing structure.

13. The existence of connecting substance (*Kittsubstanz*) between the endothelial cells is problematical. It is probable, that the dark lines, which appear at the margins of the cells on treatment with nitrate of silver, represent little drains or gutters for the serous fluid.

14. The *Saftkanälchen* of Von Recklinghausen are artificial products of the treatment with silver.

15. The mother-substance (*Mutterboden*) for the lymphoid corpuscles of the serous fluids is most probably endothelium.

WILLIAM STIRLING, D.Sc., M.B.

NAWALICHIN ON THE LYMPHATICS OF THE THYROID BODY.—J. Nawalichin (of Kasan) thus sums up the results of his researches on the lymphatics of the thyroid body. The glandular follicles of the thyroid are not limited directly by the stroma of connective tissue, but are separated from the latter by lymph spaces, so that each follicle lies in a lymph lacuna. The blood-vessels of the gland are surrounded by similar spaces, which are, however, drawn out lengthwise. By injection through the puncture (*Einstich*) method, the mass is poured out around the glandular follicles and around blood-vessels which lie in the stroma; it then collects under the connective tissue capsule of the gland, and penetrates lastly into the lymphatics which escape from the hilus, and are connected with the lymphatics lying above and below. On injecting a solution of nitrate of silver (0.5 per cent.), the above described lymph-spaces of the thyroid are lined with a single layer of epithelium. The blood-vessels lying within the lymph-spaces are also covered with such epithelium. From this Nawalichin concludes that the lymphatic system of the thyroid is a perivascular one. According to Nawalichin, the thoracic glands possess a similar lymphatic system.

WILLIAM STIRLING, D.Sc., M.B.

SCHUMKOW ON FILLING OF THE LYMPHATICS OF THE PERICARDIUM.—J. Schumkow describes (*ibid.*) his experiments on filling in a natural manner the lymphatics of the pericardium. The first thing to do in the natural injection of the pericardial lymph-vessels is to empty them of their contents, because the presence of the latter, through the formation of precipitates with the watery solution of Prussian blue employed, causes unsurmountable resistance to the absorption of the mass. The pericardium and heart having been removed together, a solution containing 6 per cent. of chloride of sodium is introduced through an opening made in the lower part of the pericardium, and, when the cavity has been thoroughly washed out, the whole preparation is gently pressed in a wet towel. Into the cavity of the pericardium, thus washed, a certain quantity of solution of Prussian blue is introduced through the above-mentioned opening. A cannula is tied into this opening, and the preparation is inverted with

the base of the heart looking downwards. The last task in the injection consists in the imitation of the physiological variations of the negative pressure within the pericardium, caused by the movements of the heart and respiration. This is accomplished by rhythmical suction-movements, produced by applying the mouth to the cannula. In this way, there appear at first on the inner surface of the pericardium, tolerably parallel blue lines; then there come into view in the deeper layers of the pericardium, branches running at right angles to the first-named twigs; and lastly, on different portions of the outer surface fine networks, characteristic of lymphatics, become visible. These nets become united with larger stems provided with visible valves, and are in connection with the neighbouring lymphatics lying near the base of the heart. These injections are most successful on the heart of the calf and of the dog.

WILLIAM STIRLING, D.Sc., M.B.

NAWALICHIN ON THE VASO-MOTOR SYSTEM.—Dr. I. Nawalichin (of Kasan) communicated (*ibid.*) the results of some experiments relative to the vaso-motor system. He investigated the point whether the vaso-motor phenomena occur simultaneously, and with relatively equal strength, in all parts of the arterial system. Simultaneous measurements of the blood-pressure were made in peripheral portions of two arteries; in the case given, the carotid and femoral. Curarised dogs and cats were employed. The vaso-motor phenomena were produced either reflexly or directly by irritation of the vaso-motor centre. The reflex actions were produced either from the vagus or from the sciatic nerve. Direct stimulation of the nerve-centre was produced either through a diminished supply of arterial blood to the same (compression of both carotids), or through disturbed arterialisatation of the blood (interruption of the respiration.) The following were the results.

1. Central stimulation of the vagus nerve generally produces a pronounced change in the blood-pressure in the peripheral portion of the carotid, which consists in an increase or diminution, without there being a corresponding change of the pressure in the peripheral end of the femoral artery. It sometimes happens that, during the increase of blood-pressure in the carotid, the pressure in the femoral sinks.

2. Central stimulation of the sciatic nerve causes in the majority of cases an increase of pressure in the carotid, but not in the femoral. Cases occur where the pressure in the femoral also rises, but the maximum occurs later than in the carotid.

3. Occlusion of both carotids (in cats) causes an increase of pressure sometimes in the one, sometimes in the other system.

4. Interruption of the respiration increases the blood-pressure in both systems; the increase, however, begins sooner in the femoral, increases equally and lasts longer, so that the maximum pressure in this vessel is absolutely and relatively greater than in the carotid.

The above facts show that the changes in the different vessels caused by the vaso-motor system are not only unequal with different forms of stimulation of the centre, but that they are also not simultaneous with the same mode of stimulation; and that they may be of different strength, and may even run in opposite directions. This is true not only of different animals, but also of one and the same animal, at different times.

WM. STIRLING, D.Sc., M.B.

SPIRÒ ON INNERVATION OF THE GLOTTIS IN THE FROG.—Dr. P. Spirò (Odessa) read (*ibid.*) a communication on the innervation of the glottis in the frog. The chief results of the experiments described in his paper are the following.

1. The reflex centre for the muscles of both valves of the glottis lies in the lower two-thirds of the medulla oblongata, and the one for each valve lies in the corresponding half of the medulla. If the medulla be divided at the upper limit of the above named region, the play of the valves ceases, although a peripheral stimulation produces a single opening of the glottis.

2. A continued peripheral stimulation (stimulation of the sciatic nerve with a weak induced current) produces a rhythmical play of the valves.

3. The normal rhythmical action of the glottis depends upon the middle portions of the brain. This dependence can be explained by supposing either that from the parts named, under normal circumstances, periodic impulses proceed for the action of the reflex centre of the glottis, or that the portions of the cord lighten somewhat the work of the reflex centre. That the reflex centre can act rhythmically alone and for itself has been shown; the second possibility is therefore the more probable one.

4. If the medulla be divided into two halves by a longitudinal section, the normal play of the valves remains undisturbed.

5. When the vertical section is prolonged upwards to the thalami optici, there occurs a complete disturbance in the co-ordination of the movements of the valves. The rhythm of the play of the valves on the two sides becomes quite different. These experiments seem to show that the co-ordinating centre for the valves is placed in the mid-brain.

6. When, however, a longitudinal section is carried through the upper third of the medulla and through the whole brain, whilst the lower two-thirds remain intact, no disturbance in the co-ordination occurs. The simplest explanation of the last three experiments would be that the connection between the reflex centre for both valves lies not only in the medulla oblongata, but also in the mid-brain as far as the thalami optici. The rhythmical motor apparatus of the glottis has two accessory arrangements in the brain; one has an inhibitory action, the other an exciting one. The former lies chiefly in the lower two-thirds of the hemispheres, the second predominates in the corpora quadrigemina.

7. A section through the lower third of the hemispheres restrains the movement of the glottis. The same follows the beginning of the stimulation of this spot by means of chloride of sodium or weak currents, as well as by stimulation of the optic thalami with weak induced currents.

8. The first effect of section and stimulation of the corpora quadrigemina consists in an acceleration of the movements of the glottis. Very weak induction-shocks produce only an acceleration; somewhat stronger currents cause accelerated and stronger movements, which ultimately pass into a continued opening of the glottis.

9. If the above stimulation be proceeded with, then there follows, after the period of increased activity, an interval of rest, which gives place to an increased activity, then follows rest, and so on.

The experiments on the influence of continued stimulation of the sciatic nerve led to the following results.

10. A weak induced current produces a very transient acceleration.

11. The medium current yields the same effect as a continued stimulation of the middle portions of the brain (9).

12. The first effect of a strong current consists generally in a diminution of the activity of the glottis.

These experiments with stimulation of sensory nerves were made in two ways : on animals with the middle portions of the brain uninjured ; and on those in which the section described under 1. was made.

Experiments on rabbits, with stimulation of the sciatic nerve, the brain being intact, have yielded the author similar results.

WILLIAM STIRLING, D.Sc., M.B.

MATERIA MEDICA AND THERAPEUTICS.

PROUT ON AN ABORTIVE TREATMENT OF CORYZA.—Dr. J. S. Prout (*New York Medical Record*, Jan. 1, 1874) recommends the tincture of the chloride of iron for this purpose. He states that he has often been able to arrest the disease in his own case, and in that of his patients, by the administration of twenty to thirty minims of the tincture as soon as possible after the cold is 'caught.' He usually finds that, in about half an hour, there is a decided amelioration of the symptoms, and in case the improvement is permanent he gives no more, but if it does not pass off in two or three hours, he repeats the dose, if necessary, three or four times. A convenient form for prescription is : R. Tinct. ferri chloridi, glycerin., aa. $\mathfrak{z}\text{iv}$. Mix. One tablespoonful in a wineglassful of water.

LEVIS ON CARBOLIC INJECTION OF HYDROCELE. Dr. Levis (*Philadelphia Medical Times*), says : The most popular method for the radical cure of hydrocele is the injection of stimulating fluids into the vaginal tunic, after the withdrawal of the serous effusion by the trocar. Of the various injecting fluids proposed, tincture of iodine is most generally employed at the present day ; but it often fails to produce the inflammation requisite for the obliteration of the sac, and occasionally induces too much inflammatory action. Dr. Levis prefers carbolic acid for the injecting material, and in a case which he describes used one drachm of a mixture of equal parts of carbolic acid and glycerin.

The injection of carbolic acid seems, from other cases to which it has been applied, to fulfil the conditions most admirably, producing sufficient inflammatory action to secure adhesion of the walls of the sac, and giving little or no pain to the patient, either at the time of its introduction or subsequently. This freedom from pain is probably due to the local anæsthetic effect of the carbolic acid, for it is well known that, if this article be placed upon the skin, the surface can be scarified with a knife without pain.

KITCHEN ON NITRITE OF AMYL IN SPASMODIC ASTHMA AND ACUTE BRONCHITIS.—Dr. Daniel H. Kitchen (*American Journal of Insanity*, October, 1873) has employed nitrite of amyl with great success in the paroxysmal cough and dyspnoea of acute bronchitis, and in the suffocative attacks of spasmodic asthma. He gives it by inhalation, in doses of from six

to fifteen drops, poured into a small cup-sponge and applied immediately to the nose, the mouth being kept shut. He believes its beneficial effect to be due partly to its sedative action on the muscular system through the motor nerves, and partly to its power of diminishing blood-pressure and causing contraction of the capillaries. He details four cases, in all of which a variety of other remedies had been unsuccessfully tried, and in all of which nitrite of amyl gave prompt and entire relief.

CONNER ON AROMATIC TINCTURE OF ASSAFÆTIDA.—Mr. L. Myers Conner says, in the *American Journal of Pharmacy*, that this tincture has such an unpleasant smell and nauseating taste, that it cannot be given in every case required. Frequent requests of physicians to prepare a tincture that would be more pleasant to the taste, and produce the same effect without the addition of water, have induced him to make some experiments. The formula offered has been tried, the aromatics being no objection, either in properties or preparation ; it can be made at any time, also keeps well.

R. Tincture of assafœtida, U. S. P. $\mathfrak{z}\text{viij}$.
 „ orange peel $\mathfrak{z}\text{ij}$.
 Essence of peppermint $\mathfrak{z}\text{ij}$. M.

Dose, one and a half to two fluid-drachms, without the addition of water.

FORMULARIES.

VEHICLE FOR THE ADMINISTRATION OF CHLOROFORM.—A French medical journal remarks that the best course is to dissolve the chloroform in glycerine (1 in 3), which is effected with tolerable facility, and gives a very clear solution, pleasant to the taste, and with a strong odour of chloroform. This solution can be mixed in all proportions with water without the occurrence of any precipitation, though the odour is distinctly perceptible. In forming the mixture, it is well to add the chloroform slowly, and to mingle the two thoroughly. It should be left at rest for twenty-four hours ; at the expiration of this period a portion of the chloroform will be found to have collected at the bottom of the vase ; this should be separated and mixed with an additional part of glycerine, when no further separation will occur. This mixture may be kept for some time without any loss of chloroform by evaporation.

TO DISGUISE CASTOR OIL.—A writer in a Canadian Pharmaceutical journal, recommends for this purpose the following formula :—

R. Ol. ricini $\mathfrak{z}\text{j}$.
 Ol. anisi gtt. x.
 Chloroform gtt. x.

Shake well together ; then add

Mucil. acaciæ $\mathfrak{z}\text{ij}$.

Shake well, and make up with a sufficiency of water.

Mr. Gregory, in the *American Journal of Pharmacy*, says :—

For some twelve or fourteen years past I have used the following formula for a castor-oil draught, which has proved very acceptable to adults who could not get down the pure oil. For children it does not answer so well, the dose of necessity being double that of the oil :—

R. Ol. ricini $\mathfrak{z}\text{j}$.
 Mucil. acaciæ $\mathfrak{z}\text{ij}$.
 Shake well together ; then add
 Syr. simp. $\mathfrak{z}\text{ij}$.

RAW BEEF IN DYSENTERY.—In cases of chronic diarrhoea for which a diet of raw meat is recommended, the following formula may be found useful:—Take beef reduced to pulp, mix this with rum, brandy, or whisky enough to make into a soft mass, to which may be added, according to the patient's taste, either salt or sugar; several spoonfuls to be taken during the day.

OBSTETRICS AND GYNÆCOLOGY.

THOMAS ON THE USE OF A DRAINAGE-TUBE IN OVARIOTOMY.—Professor T. G. Thomas, in some clinical remarks on a case of ovarian disease (*Philadelphia Medical Reporter*, January 31) says:—‘To-day I furnish the report of the case of ovarian tumour brought before you three weeks ago. I withdrew some of the fluid with a hypodermic syringe, and found it to be clear. Last Saturday, at the Woman's Hospital, I removed from this patient a tumour weighing thirty pounds, and another diseased ovary of the size of a hen's egg. This smaller diseased ovary contained several cysts, one much larger than the others, and in a year or so it would have given her a deal of trouble. The method of operating was to cut down on the tumour, introduce a sound and separate any adhesions (the tumour in this case had very extensive attachments), seize the cyst, evacuate it with the hollow trocar, and remove the collapsed cyst. In this case the omentum had to be detached from the wall of the cyst after it was taken out of the abdomen. The pedicle was then secured in a clamp and a glass tube inserted into the abdominal cavity, then the wound sewed up.

‘This tube is of glass, about four inches long and half an inch in diameter, slightly curved. It is carried down behind the uterus, into Douglas's cul-de-sac, and the sutures in the abdominal wound are so applied as to tightly embrace it. In this case, before the operation the bloody serum was welling out of the wound, and we estimated that from it came eight or twelve ounces of fluid.

‘Within twenty-four hours the abdomen was washed out with a basin of water, containing from a dessert-spoonful to a table-spoonful of salt, and enough of carbolic acid to give it a slight smoky taste. The manner of proceeding is this: elevate the head of the bed so as to cause all fluids to drain towards the lower part of the abdominal cavity; then draw up the tube slightly, and into it insert a gum elastic catheter with its end cut off. Pump into this catheter, by means of a Davidson's syringe, the medicated water, and it will pour out through the glass tube. This washing out has to be done once or twice in twenty-four hours. From the time of the operation up to the present there have been no untoward symptoms; the temperature never rising above 101.2-10° Fahr. To-day the tube was removed, and I consider her now free from all danger.

‘In respect to the use of the drainage-tube, I consider it a most important item in treatment; I have used it in the last fifteen or twenty cases, and am very well satisfied with the results. In this last case, for instance, the twelve or fifteen ounces of fluid which came away after operation might have been absorbed, but on the other hand it would have been very likely to cause septicæmia. Every man is tempted to improve on his present method, and sometimes yielding to this is not judicious. I

thought to improve on the present tube, by making perforations around the side of it. I used it in one case and found the patient, after a few days, complain of a sensation of dragging down of the intestines. I first supposed this to be either neuralgic or hysterical. However, I tried to withdraw the tube, and found it retained in the abdominal cavity; by making sufficiently strong traction I removed it, and found that the omentum had got into the perforations of the tube, and formed minute herniæ; in some cases nearly strangulated. Should such a thing take place into the lower orifice now, the daily washing out would free it and keep it so.

‘In ovariectomy the cause of death is, as a rule, not what we should expect. I mean peritonitis. Out of forty cases, only two died of peritonitis. I do not mean that there were only two deaths; I think there were thirteen or fourteen; but in only two of them was peritonitis the cause. In the rest, septicæmia was the most common trouble.’

[We strongly object to any lecturer drawing any conclusion from a case which is incomplete. An operation is performed ‘last Saturday,’ ‘to-day the tube was removed, and I consider her now free from all danger’—is a most unsafe and doubtful foundation for any teaching.—*Rep.*]

BRANDT ON EFFECTIVE REMEDIES FOR ULCERATIONS OF THE OS UTERI.—Julius Brandt (*Medizinisch-Chirurgische Centralblatt*, March 27, 1874), in cases of chronic induration and erosions of the cervix, believes that the disease is in great measure kept up after the affection of the uterus, which in most cases is the primary cause of this affection, has been relieved, by the purulent and decomposing secretion of the vagina. To prevent this, taking care first of all to remove any decomposing matter off the sore by wiping it with a solution of chloride of lime, he applies a piece of fine charpie dipped in a preparation of one ounce of glycerine, two drachms of tincture of catechu, and one drachm of balsam of Peru, and placed carefully on the raw surface, and encases it with dry charpie, so as to completely surround the vaginal portion of the cervix. This application is used twice a day. The author mentions a case where he cured a lady in five months, who for upwards of six years had consulted innumerable doctors and tried every conceivable remedy. When there are hyperæmia and a granular state of the ulcer, he omits the balsam of Peru. The constitutional treatment should never be neglected when it arises from some internal catarrhal condition. Where it is only a slight erosion, he recommends touching the parts with the solid stick of nitrate of silver, or a solution of the same, in preference to any other application. The use of leeches should never be forgotten, especially in hyperæmic conditions of the cervix, but great care should be taken not to apply them to an eroded spot, as it only increases the mischief. Baths of salt water are of great service, but they must be persevered in regularly for months.

W. C. GRIGG, M.D.

LANDAU ON ENDOMETRITIS OCCURRING DURING PREGNANCY; ABORTION ARRESTED; INERTIA OF THE UTERUS; ADHERENT PLACENTA.—Adolf Landau (*Medizinisch-Chirurgische Centralblatt*, March 6, 1874) relates a case where he was consulted by a fine healthy peasant woman, five months pregnant, mother of two children, for a return, as she thought, of the menstrual flux. She attributed it to a blow on the abdomen, received a short time before.

It was attended with a good deal of pain in the lower part of the stomach, and fever. Presently she noticed a reddish discharge, which gradually increased, becoming very profuse and accompanied latterly with pain. The question arose whether it was one of those rare forms of menstruation occurring during pregnancy in persons of a full habit of body, which are generally very profuse when they do happen; or indirectly a detachment of a portion of the placenta; or directly a local hyperæmia of the uterus, the result of the blow, with a consecutive rupture of the uterine vessels. The latter the author believes to have been the case. Fearing a miscarriage, from the blood becoming coagulated within the uterus, increasing its size and setting up expulsive uterine action, he enjoined rest in the horizontal position, administering internally digitalis and opium, which had the effect of arresting hæmorrhage, and the woman went her full time. The labour progressed naturally until the os was fully dilated, when the pains ceased. Ergot and Indian hemp were given, but without effect. A gum catheter was then introduced between the uterus and its membranes, and rapidly induced strong labour-pains, forcing the child's head into the pelvis, when the pains again ceased. The forceps was applied and the child extracted.

The placenta was adherent to the uterus over its whole surface and with difficulty peeled off. There was considerable *post partum* hæmorrhage. Convalescence was retarded, but the patient eventually quite recovered. The writer considers the inertia of the uterus to have arisen from its muscular walls having become altered by the metritis causing an increase of the fibrous tissue, which not only interfered with their contraction but also with their nerve-supply.

W. C. GRIGG, M.D.

CASA ON SENILE GALACTORRHOEA.—Dr. Luigi Casa relates two cases in the *Gazzetta della Cliniche* for February 17. The first case was that of a woman, G. M., aged sixty-five, in whom the galactorrhœa appeared without any previous indication of disease. Her parents had been healthy, and had lived to a great age, and she had not had any disease of importance. She had had seven healthy confinements, and ceased to menstruate at the age of fifty-five, for three or four years, after which she felt quite well. When she was about sixty years old the breasts began to swell; this continued for some months, and, as she said, was greater, and was attended with increased pain, at the full moon. There was no other drainage. The flow of milk then ceased for about two years, until the beginning of 1868, when Dr. Casa was called to see G. M. On examination, he found the breasts much enlarged, measuring about ten inches from the ribs to the point of the nipple. On gentle pressure a fluid escaped, which presented no difference in appearance from milk. Notwithstanding her age, she felt considerable venereal excitement; she had also pruritus of the genitals, which, however, was not very troublesome. She had lost her appetite, and was always slightly constipated. Dr. Casa could not, on careful examination, find any disease of the external or of the internal genital organs. He gave her Bonjean's ergotin, and in a few months the lacteal discharge and all signs of mammary engorgement disappeared. She died in the same year, of typhoid fever following double pleuro-pneumonia.

The second case was that of a woman, aged about

fifty, in whom the catamenia had ceased for some years, and who died of uterine cancer about two years ago. Her mother had died of the same disease at a very early age. Early in 1871, the woman, while consulting Dr. Casa on account of the uterine disease, showed him her breasts; they were enlarged, and in the course of a few weeks there was a discharge of a fluid presenting the characters of milk, but rather denser, and of a greenish colour.

MISCELLANY.

FOREIGN BODY IN THE STOMACH.—About five months ago, says the *Philadelphia Medical and Surgical Reporter*, the infant son of Mr. J. B. Scattergood, of this city, aged four and one-half months, swallowed a fruit-knife two and three-eighths inches long, one-fourth inch thick, and one and one-fourth inches in circumference. Over four months afterwards, on March 8, the child then being nearly nine months old, the knife passed out through the bowels. During the interval the little fellow suffered very much at times, but he is now in good health.

FRENCH ACCLIMATISATION SOCIETY.—At the seventeenth annual meeting of this society lately held in Paris, M. Drouyn de Lhuys, the president, gave an interesting account of the naturalisation of coffee. He showed it, as it was in its original state, a poor and stunted plant growing in the desert plateau of Abyssinia, then gradually acquiring, up to the eighteenth century, that importance in Bourbon Martinique and Guadeloupe, which has made it one of the principal sources of colonial wealth. M. Henri Bouley, of the Institute, read an interesting paper on the domestication of animals.

OUR WEIGHTS.—Upon the average, boys at birth weigh a little more, and girls a little less, than six pounds and a half. For the first twelve years the two sexes continue nearly equal in weight, but beyond that time males acquire a decided preponderance. Thus, young men of twenty average about 143 lbs. each, while the young women of twenty average 120 lbs. Men reach their heaviest bulk at about thirty-five, when they average about 152 lbs.; but women slowly increase in weight until fifty, when their average is about 128 lbs. Taking men and women together, their weight at full growth averages about twenty times as heavy as they were on the first day of their existence. Men range from 108 to 220 lbs., and women from 88 to 207 lbs. The actual weight of human nature, taking the averages of ages and conditions—nobles, clergy, tinkers, tailors, maidens, boys, girls, and babies, all included—is very nearly 100 lbs. These figures are given in airdupois weight; but the advocates of the superiority of women might make a nice point by introducing the rule that women be weighed by troy weight—like other jewels—and men by airdupois. The figures will then stand: young men of twenty, 143 lbs. each; young women of twenty, about 146 lbs. each, and so on.

PRESERVATION FROM HYDROPHOBIA.—At the meeting of the French Academy of Sciences on April 13, M. Bouley laid before it a memoir by M. Bourrel, a veterinary surgeon of Paris, entitled a 'Complete Treatise on Rabies in the Dog and Cat, with a method of Preserving Oneself against it.' The means of preserving from rabies, to make known and disseminate the knowledge of which is the principal aim of this memoir, consists in taking off the edge of the teeth of the dog by the aid of nippers and files. M. Bourrel had the daring to perform this operation of filing down the teeth on three dogs when they were in a condition of raging madness, notwithstanding the danger of inoculation he incurred both during the preliminaries and the different stages of the process. Six dogs kept for experiment were then delivered over to the mad animals, who precipitated themselves on them and bit them furiously, but without breaking the skin in any one of them. The dogs experimented on were watched during six months, and madness did not show itself in any of the number. M. Bourrel, convinced that the blunted tooth of the dog could not penetrate through clothing, gave his hand covered with a glove to one of the mad dogs. 'When,' he says, 'the dog released it, the glove was intact, and the bite had only produced a deep impression. This experiment, repeated on dogs who were not mad, to which I gave my naked hand to bite, proved to me that the blunted tooth can but very rarely, however great may be the contraction of the muscles of the jaw, break the epidermis of animals, whose hair necessarily deadens the pressure exerted; and can only injure the human epidermis in very exceptional cases.

THE United States' Medical Directory is now passing through the press, and will be delivered to subscribers early in June. It will make a handsome volume; large octavo size, of six hundred or seven hundred pages, and is offered to subscribers at five dollars. After publication the price will be six dollars.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & Co., London; and through their Agents:—Paris: Mr. G. BOSANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S. W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MAY 6, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

THE USE OF LARGE ENEMATA.

* Prenez-le, Monsieur, prenez-le ; il ne vous fera point de mal, il ne vous fera point de mal ; il est bénin, bénin ; là, prenez, prenez, Monsieur, c'est pour déterger, pour déterger, déterger.

MOLIÈRE, *M. de Pourceaugnac*, acte i. sc. xv.

The use of clysters and purgatives in medicine has outlived the sarcasms of Molière and Rabelais, the attacks of homœopathists, and other opponents of orthodox medicine, and the more serious arguments of Skoda, Skey, and other advocates of constipation. The reasons are not far to seek ; for, whatever the theoretical advantages of loaded large intestines at all times, and the practical uses of retaining the alvine contents in certain diseases, or after such operations as herniotomy, the repair of vesico-vaginal fistula, ovariectomy, and the like, there can be little doubt that the majority of mankind cannot, with impunity, long retain accumulations of fæcal matter, reeking with poisonous gases ; and further, that such accumulations often produce serious inconveniences in a mechanical way, preventing free movements of the diaphragm and abdominal muscles, thus hindering respiration, as well as locomotion ; preventing absorption and free circulation of blood—thus inducing marasmus on the one hand, and a tendency to inflammatory stasis and dropsy on the other. Of all the ways of relieving over-loaded bowels, and of softening hardened scybala, none are at once so gentle, and so efficacious as enemata—especially large ones. We have already given our readers a summary of the views of Gustav Simon, Alfred Hegar, F. Mosler and Wilbrand, on this subject, in vol. i. no. 47, p. 747, and vol. ii. no. 56, p. 50. We shall therefore content ourselves, now that the matter has been freely discussed in the German medical papers, with giving a summary of the general results of the discussion, and the practical outcome of the experimental trials of this method. Those who wish for more detail will find the whole subject carefully and fully discussed in the *Allgemeine Wiener Medizinische Zeitung* for March 3, 10, 17, 24, and 31, in articles based chiefly on matter contained in G. Simon's article in *Langenbeck's Archiv für Klinische Chirurgie*, vol. xv. part i. ; Alfred Hegar's work, *Ueber Einführung von Flüssigkeiten in Harnblase und Mastdarm* (Freiburg : F. Wagner) ; Wilbrand in the *Berliner Klinische Wochenschrift*, no. 49 (1873) ; F. Mosler, in the same journal, no. 45 (1873) ; reports in the journals of the discussions at Wiesbaden on September 20, and subsequent experiments in the Heidelberg Hospital—the essence of which has already been laid before our readers. We have hinted before, and we take this opportunity of

reminding our German friends, that there is but little new in this discussion. The advantages of large enemata, the use of an apparatus like an irrigator, have all been familiar to English surgeons and physicians for many years. Even the instruments, or, at all events, some on precisely the same principle, were exhibited at the Obstetrical Society's conversazione in 1867—and cases like Wilbrand's have occurred again and again in both hospital and private practice—as long ago as Dr. Bright's time, it at no earlier date.

Mosler's experiment on Simon's patient with a fæcal fistula (see LONDON MEDICAL RECORD, vol. i. p. 747), is, however, a valuable confirmation of the views which have long been held by practical men. And the whole discussion is valuable, as tending to simplify and strengthen our faith in simple methods of treatment. It seems to us, that the following are the practical results.

1. Enemata, if sufficiently copious, will reach the small intestine, the ileo-cæcal valve notwithstanding, provided there be sufficient propelling force, whether that be gained by a long column of fluid in the apparatus (as in the use of irrigators), or by the patient's position, with the pelvis elevated, favouring the descent of the fluid, or by repeated action of the injecting instrument. For ourselves, we could never see that the valvula Bauhini could ever be regarded as a real obstacle to injections from below, provided these were sufficiently copious ; and we had made some experiments at different times, which had given ocular evidence of the extent to which injections had penetrated.

2. Hegar's and Mosler's experiments, and Wilbrand's case, show that it is neither necessary to use complex apparatus, nor to put the patients into awkward and perhaps dangerous positions ; since from three to five feet of pipe, with a funnel at one end and a suitable nozzle at the other, is all the apparatus we need ; and the patients simply lie upon the back, and the only pressure required is that of the column of fluid. We may here remark, parenthetically, that we fail to see the pertinency of the long discussion about atmospheric pressure, sub-atmospheric pressure, and the like ; because, whether in or out of the body, making allowances for temperature and the varied characters of the gases, we take it that atmospheric pressure may be regarded as a fairly constant unit ; were it otherwise, learned professors and their poor patients would alike be crushed by the superincumbent air. The real pressure we have to overcome is that of the patient's muscles—aided in some cases by tense gases in the bowel ; for, if anyone will insert a tube into the rectum before the injection has come away, he will see the fluid come out in jets or sprits when the patients strain, and less markedly so at every descent of the diaphragm. In certain positions of the body, there is also the difficulty of 'making the water run up-hill,' when we are administering an enema in the ordinary manner—ingeniously overcome by Hegar and Mosler, either by making the water run down-hill (or rather down a long tube) first, or by shifting the position of the patient.

3. The safety and efficiency, or, to quote Molière against himself, the benign action of large enemata of water, gruel, and the like, is strikingly shown by these experiments. We are strongly inclined, however, to believe that a very small quantity of soap, or of some neutral salt, is even less irritating to the mucous membrane than pure water alone. Ex-

cept in rain-water, or in water which has been frozen, man no where finds anything like a pure drink provided for him; and what is true in a superior sense, and, so to speak, *à priori*, is, we think, no less true *à posteriori*.

4. As regards *priori* in these questions, we have already partially disposed of that. But Simon seems to have been singularly fortunate in having patients with fistulæ high up in the bowel. Hegar and Wilbrand appear to have worked separately, and ingeniously, at the same subject; and Mosler appears to us to take the widest and most advanced views, and, so to speak, 'to grasp' the subject better than the others. To Mosler also belongs the credit of the crowning experiment recorded in our previous number, quoted above. It seems, however, not superfluous to remark that the advantages of *position* claimed by Hegar and Wilbrand are not confined to the mere introduction of the fluid. There are cases in which it is not only desirable to gain admittance for the clyster, but also to keep the warm fluid in close contact with the hardened fecal masses. This would be more particularly necessary, if, as Simon suggests, large nutrient enemata be given to sustain life, in exhausting diseases, such as cancer of the stomach.

5. The caution impressed upon us by these experimenters, not to allow air to get into the bowel, or as little as possible, is not an idle one. A very small quantity of air is not only intensely irritating to the bowel, but gives the greatest pain, almost agony in many cases. This fact was well known to our forefathers, although some of the so-called 'trained nurses' of the present day, and many practitioners even, seem ignorant of it. Unless the precaution be taken to exclude air, the clyster is certainly not benign. To sum up all, large injections do reach the whole length of the large intestine, and beyond it; they are safe and speedy remedies for fecal accumulations, for some forms of intestinal obstruction (notably intussusception) and internal herniæ; for the treatment of intestinal ulcers, of hæmorrhage from the bowels and diarrhœa; for worms, especially oxyurides, and their congeners; as a means of stimulating and increasing the secretion of bile; and of introducing into the small intestine nutritious matters in a state easily susceptible of absorption.

Lastly, the Vienna reviewer adds with justice, that the use of the irrigator apparatus (or of the long tube and glass-funnel) is a likely method of overcoming meteorism which might otherwise defy remedial measures—since it is easy for the bubbles of gas to escape through the fluid, as they did in Wilbrand's case.

W. BATHURST WOODMAN, M.D.

COLIN ON THE ASHANTEE EXPEDITION.*

M. Léon Colin, Professor at the Val-de-Grâce Hospital in Paris, in a paper published in the *Gazette Hebdomadaire de Médecine et Chirurgie*, and since printed separately, gives a brief sketch of the West Coast of Africa in its medical and hygienic aspects, derived both from English records and from the results of the French occupation of Senegal, &c. The principal dangers to health are touched upon, and the chief diseases that are likely

to be met with enumerated, with a glance at the various means of prophylaxis. An account is also given of the means undertaken for the recent expedition, and a reference to some of the former wars of the kind, particularly the disastrous one of Sir Charles Macarthy, with a survey of the probable chances of failure or success. The author gives due credit to the preparations made for the recent campaign, saying, 'It is only necessary to recall the admirable results of the campaign of the English in Abyssinia and the worth of the epidemiologists, of which that nation has a right to be proud, in order to be certain beforehand that we shall have in this struggle the consoling spectacle of the most energetic efforts placed at the disposal of the most advanced science in order to combat its chief perils.' He lauds also the practical good sense of the English people, who appreciated the importance of the commander of the expedition carefully organising the details of the campaign prior to the arrival of the European troops.

Premising that it affords the keenest interest to the medical men of all countries to follow the course of this campaign as one less against a human enemy than against 'l'imminence morbide,' inseparable from such a terrible climate, M. Colin reviews briefly the chief types of disease likely to be encountered. Among them, the yellow fever has now comparatively little interest for us, seeing that the history of the campaign has been happily free from that terrible scourge. But the remarks on paroxysmal fevers (*fièvres palustres*) have a strong bearing upon the health of our little army. Under this head he includes all attacks of a febrile character, from heat-apoplexy, where the thermic influence predominates, to fatal bilious remittent, where the telluric influence is at its maximum; although he very properly draws a distinction between this class and sunstroke proper (*sideration solaire*) which ought not to be considered in the same category. Quoting Thévenot, he remarks, 'In Senegal, remittent fever is generally the disease of those whose blood is rich and strength still intact;' and this is borne out by present experience, as the short campaign seems to have told most severely upon those who appeared to be physically the strongest; whilst the less robust, when they have escaped dysentery, appear in many cases to have borne the climatic influence fairly well. The prognostication that there would be few cases of dysentery, on account of the precautions taken and the excellency of the diet, have been fully borne out. As regards Guinea-worm, little or nothing has been heard of it among our troops.

In considering the question of prophylaxis, M. Colin throws doubt on the efficacy of quinine as a preventative, but admits that in a country like the west coast, where the malaria is so intense, it is of value, although he appears to look upon it more as a curative agent of malaria immediately absorbed than as actually guarding against future attacks. He justly lauds the precautions taken to keep the troops on ship-board until actually wanted, and not landing them until they could set to active work at once. There can be little question that enforced inaction is one main cause of predisposition to disease in a tropical climate, besides the temptation it gives to intemperance and debauchery, thereby increasing the receptivity of morbid influences. At the same time, he points out from the results of former campaigns that the dangers that the Ashantees have to encounter are at least equal to our own, and he recalls

* *L'Expédition Anglaise de la Côte d'Or, Étude d'Hygiène militaire et de Géographie médicale.* Par M. Léon Colin, Professeur au Val-de-Grâce. (Paris, 1874.)

the result of Sir C. Macarthy's disastrous campaign, when they were obliged to retreat from Cape Coast Castle, more than decimated by dysentery and small-pox. Such, he thinks (quoting Admiral Henriot de Langle) might be the result of the present war. Happily, however, we have been able to teach them another lesson, and one they are not likely to forget, even although the treaty may not be effectually carried out. At the same time it must be admitted that, successful as our operations have been, the dangers of the advance on Coomassie were by no means imaginary, and that a rare good fortune converted into a signal success a series of operations which might at any time have become a fatal disaster. An account, written in the highest terms of admiration, is given of the arrangements of the *Victor Emmanuel*, and its immense importance is fully recognised. The working of this vessel has been one of the most valuable features of the whole campaign, as well as a powerful element of its success. That the officers on board should have been so far ignored as not to be mentioned at all in dispatches, or even officially recognised as part of the expedition, is surprising, but it is satisfactory to know that the work done was thoroughly known and appreciated by the present head of the Army Medical Department, and the conferring of the Order of the Bath upon Surgeon-Major Bleckley is a just recognition of the value of the service done, and the excellent way in which it was carried out. A well-deserved tribute of praise is given by Dr. Colin to the services of Dr. (now Sir Anthony) Home in organising the medical and hygienic arrangements of the expedition, to which services the final triumph was in a large measure due, although he himself was unfortunately deprived of the opportunity of personally witnessing it.

In conclusion we may say that the happy results of so arduous and dangerous a campaign, coming after the signal successes of Abyssinia and North China, may well make us proud of the medical departments of the public services, and convince us that, in spite of the many disadvantages and prejudiced opposition they have to encounter, they have shown themselves second to none, and have worthily maintained their high reputation for professional skill, administrative capacity, and self-sacrificing devotion.

J. MACPHERSON, M.D.

ESMARCH ON BLOODLESS OPERATIONS.

The following is a brief abstract made by Professor Esmarch of his experience during the past year of his practice in Kiel, of bloodless operations. The communication was made at the third sitting of the German Surgical Association, held in Berlin, April 8th to 11th, 1874. After a few preliminary remarks, Professor Esmarch detailed the following statistics.

From February 1, 1873, to April 1, 1874, above two hundred bloodless operations were performed in the Clinic at Kiel. Amongst them were the following:—

Amputations.

Thigh, ten cases; one died, with erysipelas and septicæmia.

Leg, eleven cases; one died, with ditto.

Humerus, three cases; none died.

Total: twenty-four cases, with two deaths.

Disarticulations.

Shoulder-joint, one case; cured.

Hip-joint, one case; died of exhaustion.

Total: two cases, with one death.

Resections.

Hip-joint, three cases; one died, of septicæmia.

Knee-joint, three cases; none died (one with subsequent amputation).

Elbow-joint, two cases; none died (one with subsequent amputation).

Total: eight cases, with one death.

Amongst the advantages of the bloodless method of operation, the following may be mentioned.

1. There is no loss of blood. (Anæmia produces a disposition to surgical accidents, by the tendency to coagulation producing thrombosis, and leading often to pyæmia. Valsalva's method of treating aneurism acts by inducing greater coagulability of blood.)

2. It is a great advantage that sponges may be thus almost wholly avoided; for, with whatever care they are disinfected, one can never be absolutely certain that they are not sometimes the means of infecting wounds.

3. The larger arteries and veins are less injured in the bloodless method, than with ordinary digital or instrumental compression, the constriction being uniform, circular, by means of the soft parts, and distributed over a large surface.

Esmarch knows of no dangers, nor of any bad results. Paralysis he has never seen to take place. It may be produced, however, by too forcible constriction of the limb. Esmarch applies the apparatus himself, and does not trust his assistants, who are rather inclined to overdo their business. It is quite remarkable how comparatively small is the force necessary to arrest all flow of blood through the arteries. The first turns must not be made too tightly: every superimposed turn increases the compression very considerably.

Gangrene has not been observed in any instance by Esmarch. Some probable advantages of bloodless operations may be shortly hinted at.

1. Local anæsthesia may take place after a few minutes. Richet has indeed already recommended forcible constriction of the digit for the operation on ingrown nail. Richardson's ether-spray, or ice and salt, produces anæsthesia much more quickly in parts made bloodless, as the warmth of the blood is excluded. The temperature of the bloodless limb sinks immediately.

2. Diseased parts, bones, joints, can be very easily examined before performing an operation. Esmarch narrated very graphically how on a recent occasion he demonstrated a diseased joint before his class, pointing out the conditions which made an amputation necessary.

3. Foreign bodies, splinters, needles, &c., are easily found.

4. Wounded arteries are easily exposed and secured. Antyllus's method is facilitated.

5. Operating without skilled assistants, or indeed without assistance at all, becomes possible in a way never before practicable. Esmarch has received many letters of thanks from surgeons in various parts of the country.

6. It is suggested that death may be often averted, and cases of hæmorrhage and transfusion avoided in anæmic persons, by bandaging the extremities, in order to temporarily drive the blood of one or two extremities into the body.

An elastic tube is the most proper thing for general use, because it can be employed in all places. An elastic roller can be employed in many cases just as well, but its use must be learned. Bloodless operations can be performed at the shoulder or hip-joint. The tube is applied as in the form of a single turn of spica bandage, the two ends crossing each other in the groin in the case of the hip-joint, or over the acromion in the shoulder. They are held on the stretch by an assistant, and this way the axillary and the common femoral may be completely controlled. For compression of the aorta and external iliac, a pad, or roller, must be used with the elastic tube.

WILLIAM MAC CORMAC.

FORENSIC OPHTHALMOLOGY.

ON INJURIES OF THE EYE IN THEIR MEDICO-LEGAL RELATIONS. BY PROFESSOR ARLT, OF VIENNA.*

(Continued from page 260.)

11. *Stretching and Laceration of the Zonule of Zinn.*—In order to form a sufficient diagnostic and prognostic appreciation of the changes which affect the zonule, and subsequently the lens, in consequence of concussion, we must first make some recapitulatory remarks on the importance of this structure.

It is the zonule which secures the lens in its groove. The position of the posterior capsule on the vitreous body is interfered with, as soon as the zonule has ceased, entirely or in a great part of its circumference, to connect the lens firmly with the ciliary processes. By virtue of its breadth between its insertion into the anterior capsule and the apex of the ciliary processes, it allows, without injury to the connection with the vitreous body, the crystalline lens to move forwards and backwards, and even sideways, although such changes of place do not occur in the physiological state. The lens can move two or three millimètres forward (when the aqueous humour is drawn off), and probably as far backwards (when the vitreous body escapes through the sclerotic), without laceration of the zonule, provided that the motion be not sudden.

The zonule may be stretched without laceration to two millimètres, and perhaps even more, if the extension be made gradually. We see this in high degrees of myopia, and in the so-called buphthalmus, as well as in staphylomatous distension of the globe in the neighbourhood of the ciliary body; we find it in eyes in which the lens is concentrically contracted or drawn forward towards a corneal cicatrix; and a partial stretching can also be observed in congenital ectopia of the lens.

If such stretching be continued, a more or less extensive (even total) laceration of the zonule may follow, without any cause or with a trivial one, and still more after violent concussion of the eye or of the head. While thus in one case a displacement of the crystalline lens is to be ascribed simply to a violent blow, etc., it may in another be the result of a special condition of the body of the injured person, viz., of his eye. Before, then, forming a judgment as to the force with which the injury was inflicted, the condition of the eye before the injury must be ascertained

as well as possible. Congenital ectopia of the lens, which predisposes to total separation of the lens from its natural connection, reveals itself not only by shortness and weakness of sight, but is almost always found to be bilateral. A high degree of myopia, also generally bilateral, but sometimes also unilateral, is indeed met with also after injury, at least when this has not produced perforation of the globe.

12. *Diagnosis of Subluxation of the Crystalline Lens.*—The zonule of Zinn resists the tendency of the lens to assume a spherical form, and keeps it flattened to a certain degree. When this force is removed by extensive or total laceration of the zonule, the transparent lens is reduced in the equatorial and increased in the axial diameter. The eye is rendered myopic by this change of form in the lens, and the movement of the lens from the retina towards the cornea can only increase this ametropia.

With complete peripheric destruction of the zonule, an essential factor of accommodation is at the same time removed; thus the object of direct vision must be brought before the eye at a fixed distance, in order that the rays from it may unite on the retina.

As soon as the lens ceases to be drawn on by the ciliary processes, it is thrown by the movements of the eye into oscillations which are communicated to the iris, and appear as quiverings or shakings of this structure after the lens has come to a stand. This symptom, however, has in itself no positive value, as, when the lens is transparent, it cannot be determined with certainty whether the vibrations of the iris are connected with mobility of the lens. The iris may be thrown into vibrations independently, when it is free at the pupillary border, and more aqueous humour is collected behind it than in the normal state. In cases of myopia with a deep chamber such vibrations may not unfrequently be observed to take place in a large circle of the iris; and in adhesion of the vitreous body with the deep layer of the lens, extensive vibrations of the iris are very often seen.

13. *Distortion of the Lens.*—After partial, and under some circumstances also after total laceration of the zonule, the crystalline lens may for some time remain lying in front of the vitreous body, but so that its axis does not correspond, or but slightly, with the axis of the eye. In some rare cases the lens is thrown into an oblique direction, so that one part of its edge reaches further forward; and then it is also drawn more or less laterally, so that the more posterior part of its edge lies nearer the ciliary processes than the anterior. From this there results, along with the changes described in section 12, not only a more or less marked impairment of the acuteness of vision through irregular refraction (astigmatism), but also a valuable diagnostic sign—unequal depth of the chambers. The portion of the edge of the lens that is pressed forward pushes the corresponding part of the iris forward.

When the pupil is strongly dilated (pathologically or artificially) the distortion of the lens may sometimes be recognised by ophthalmoscopic examination. The border of the lens appears as a dark meniscus, the light refracted from the fundus oculi being prevented from reaching the observer by total reflection at the edge of the lens; while, through the lens (if it be still transparent) as well as through the openings between the edge of the lens and the ciliary processes, the fundus oculi is clearly seen, provided

* *Wiener Medizinische Wochenschrift*, April 18, 1874.

that there be no sanguineous effusion or its results in the vitreous body, nor any raising of the retina.

14. *Lateral Displacement of the Crystalline Lens.* In consequence of the total reflexion of the light which is thrown on the eye of the observer from the edge of a transparent lens still in its capsule, a portion of the edge appears as a shining meniscus, reminding one of a drop of oil floating on water. This phenomenon may be observed in certain positions, as soon as the lens is so far dislocated that the view of it is not obstructed by the iris; and it may be also seen with the naked eye when the lens lies in the anterior chamber, or when a part of its edge, lying behind the iris, extends into the pupillary region; or with the ophthalmoscope, when the lens is deeply pressed on or sunken in the vitreous body. In the latter case, the patient may complain of seeing a dark ring, or a dark disc somewhat lighter in the centre; this occurs when the relations of the position of the lens and of the entrance of light are such, that, in consequence of the total reflection of the light from the edge of the lens, the portion of retina lying behind it is obscured.

If the lens, while yet in its capsule and transparent, be dislocated so as to occupy only a portion of the pupillary region behind the iris, double vision in the one eye may be the result. If such a lens be sunken so far behind the iris that its upper edge reaches about half way through the pupil, the upper portion of the light from a distant point will pass through the cornea, the aqueous humour, and the vitreous body, to the retina in the region of the macula lutea, forming a dispersion circle (an indistinct image), since the rays in question can only converge to a point behind the retina; the lower portion, on the other hand, passes through the upper section of the lens, and hence the rays not only converge in front of the retina (as in the myopic eye), but are refracted downwards, as this section acts as a prism (with the base directed downwards); the rays that have passed through the lens, having converged in front of the retina, also form an indistinct image below the macula lutea, and it will seem to the patient that, above the object directly seen, he sees a second. By a suitable approximation of the object, a position may be found, in which the rays passing through the lens do not converge before but on the retina, and on the other hand, the refraction of the upper rays may be corrected by the use of a convex glass. It is self-evident that, in examining such a case, account must be taken of the condition of refraction in the eye.

Prognosis and Treatment.—Subluxation of the lens is followed by permanent disturbance of vision, which, even in the most favourable case, renders impossible sufficient sight for reading, writing, sewing, &c. Experience shows that sooner or later (perhaps after many years), it leads to opacity of the lens, either of itself or through the changes produced at the same time in the choroid or vitreous body, or it passes, either spontaneously or under the influence of slight causes, into complete luxation.

It is not probable that lacerations of the zonule, which allow partial displacement of the lens, can be healed in such a way as that the lens regains its normal position and firmness. Nor is it probable that the results can be in any way averted by dietetic treatment. It would exceed the limits of these remarks to describe the circumstances in which the condition of the patient may be rendered more

bearable or less perilous by iridectomy, iridesis, or replacement of the lens. The eye remains permanently maimed.

(To be continued.)

MEDICINE.

LAWRENCE ON A CASE OF INTRACRANIAL TUMOUR.—Dr. S. Lawrence, of Montrose, read the history of this case before the Medico-Chirurgical Society of Edinburgh, on February 4 last, and has since reprinted it in a pamphlet form. He thinks that for clinical purposes, we may class all intracranial diseases, especially tumours and adventitious formations, in four groups, viz. :—1. Those presenting such marked special and general symptoms as to indicate, not only their existence, but also their seat. 2. Another group, in which the local and constitutional ailments point strongly to the existence of such tumours, but throws little or no light on their special location. 3. A group, in which the symptoms are altogether misleading, withdrawing the attention of the physician from the brain and fixing it on some distant organ, say the stomach or the liver. 4. In a certain number of cases the adventitious formation is altogether latent, having lain for months, or perhaps years, embedded in the brain, without giving any outward sign, direct or indirect, of its existence, and is at length only brought to light by *post mortem* examination after the subject of it has died of some other disease. Dr. Lawrence's patient was a house-painter, aged twenty-one. Much of his time was spent in book-keeping. Without any premonitory symptoms, or any apparent cause, he was seized in the night of December 15-16, 1868, with violent headache and vomiting, followed by incoherence, and then more or less stupor. Pulse, 54-60, labouring, but steady. On the 19th he had less pain, less stupor, but strabismus; his pupils were more contracted than natural, but sensitive to light. During the next ten days the serious symptoms subsided. On the 30th he had 'improved in every way, excepting squint, which continued.' About the middle of January his convalescence was interrupted for a day or two by an attack of vomiting. The strabismus persisted several weeks, and was the last symptom to disappear. In due time he resumed business, and during the latter part of 1869, and throughout 1870, continued his occupation, and remained in perfect health. In the first week of January, 1871, he was carefully examined for a life-insurance society, but the utmost scrutiny failed to detect any trace whatever of the dangerous illness through which he had passed upwards of two years before, or any flaw in his general condition. On March 14, 1871, he was visited, and had suffered for fourteen days from pains in the head and slight giddiness. At the end of the month there was a slight exacerbation and febrile symptoms. Leeching, free purging, and perfect quietude brought much relief. But on April 7, giddiness and pain returned. Early in May he had much improved; but on May 28 'giddiness and *dimness of sight* are troublesome . . . the bowels are inclined to constipation.' On June 12 the dim vision was confined to the left eye. On September 30, he could with difficulty discern any object with the left eye; the sight of the right eye was also becoming impaired. His gait also had become a little unsteady. On Octo-

ber 10, he was quite blind in the left eye, and the sight of the other eye was very dim; pain at the back of the head. On the 16th he had slight syncope. On November 1, the entry is 'there is now almost total blindness.' In December he was more closely confined to bed, finding dorsal decubitus the position that gave him the greatest immunity from pain. He became extremely sensitive to noises, which were always followed by more or less pain. January, 1872, passed without any change. On February 17 he had an attack of vomiting; also the next night. On the 22nd, after an exacerbation of pain in the head, he was seized with an epileptiform fit. On the 23rd, vomiting recurred. On March 11 and 26, there was recurrence of epileptiform seizure, on both occasions whilst sitting, and after slight exertions. During April, the weakness of the lower extremities increased. From this time to the end of October, there was no marked change. He was cheerful; but was confined to bed, as he could scarcely sit up. He was quite blind; his pupils were widely dilated, and insensible to light. During December, any attempts to raise the head from the pillow were followed by unconsciousness, as well as pain. During January, February, and March, 1873, his intellect remained clear; he had almost complete motor paralysis, but no anæsthesia. On April 12, between four and five p.m., he was suddenly seized with severe pain in the head, and vomiting. His mother applied cold to the head, and heat to the lower extremities, and he seemed to feel relief; but on being left for a few moments, he was found dead when his friends returned to the room. At the *post mortem* examination the brain was bulged out, and fluctuated; the convolutions were flattened, the spaces of the sulci obliterated. The lateral ventricles contained more than 12 ounces of clear serous fluid. On removing the brain, a loose gelatinous tumour was found to occupy the base. From its semi-fluid consistence, it was impossible to define exactly the boundaries of this body, but it occupied the fourth ventricle, and extended in front of the pons Varolii, spreading as far forward as the optic commissure, under the arachnoid. In the substance of the gelatinous mass in the fourth ventricle there was a small recent clot, about the size of a pea. The substance of the tumour, examined under the microscope, exhibited small round nucleated cells, about the size of white blood-corpuscles.

[The Reporter regrets that space does not admit of his incorporating the pertinent and interesting remarks of Dr. Lawrence on this case. There are two or three omissions in the report, which, it is possible, may yet be supplied by Dr. Lawrence. For example, there is no reference to the family history of the patient, nor to the history of his infancy and childhood. Secondly, the results of ophthalmoscopic examination are not mentioned; and in the numerous and instructive references to authorities, the more modern researches of Bouchut, Hughlings Jackson, Clifford Allbutt, and others are ignored. Thirdly, we are not informed whether the intercurrent attacks of headache, vomiting, &c., were accompanied or preceded by elevations or alterations of temperature. Lastly, we can only infer, since no clear statement is recorded, the absence of tubercular or other disease of the lungs or other organs.—*Rep.*]

W. BATHURST WOODMAN, M.D.

WENZEL ON ICED WATER INJECTIONS IN DYSENTERY.—Dr. Bodo Wenzel had opportunities of

treating numerous cases of dysentery, whilst surgeon to a ship sailing to and from Havanna, New Orleans, and New York, and also whilst he was on shore at these places. He records the result in a brief communication in the *Berliner Klinische Wochenschrift*, for December 1, 1873 (no. 48). He says that, of all the remedies against this disease of which he had experience, the most reliable was one of the most simple, inexpensive, and free from danger. It consisted in the use of clysters of iced water, containing finely pounded ice. He believes this mode of treatment to be novel, or, at least, to be seldom applied. He was induced to try it, by having on a voyage from New York, a very severe case of dysentery under his charge. The patient had high fever, great pain in the belly; and, besides very frequent action of the bowels, there was extremely severe hæmorrhage, which at one time threatened to be fatal. To check this he employed these iced enemata, every two hours. The effects were so beneficial, in reducing the fever, relieving the tenesmus, checking the diarrhœa, and relieving the pain, as well as stopping the hæmorrhage, that all other medication was left off—and one of the severest cases of dysentery ever seen was practically cured in fourteen days. Similar favourable results were attained in other cases. Dr. Wenzel, however, has not found the same brilliant success in chronic and relapsing cases; and he therefore concludes that, in all recent acute cases, an energetic local antiphlogistic treatment is a very efficacious, if not the most efficacious, remedy against dysentery.

W. BATHURST WOODMAN, M.D.

FOLLET ON A SIGN OF THE COMMENCEMENT OF DIABETES.—Dr. Follet (*Revue des Sciences Médicales*, April 15) states that a lady, aged twenty-six, showed all the outward signs of the most robust health, but complained of feelings of weight after meals, accompanied by giddiness and hot flushes. But some of her finger and toe-nails had fallen off, leaving the subungual dermis covered with a fine pink epidermis, showing no change whatever. There was no trace of inflammation in the matrix around the circumference of the nails. The father of the patient, who was not syphilitic, had seen his nails fall off in the same way, without pain or suppuration; and eighteen months after the appearance of this accident, he died of diabetes. This information induced M. Follet to examine the urine of the patient, in which he found six grains of sugar to the litre.

In this case there was doubtless a circulatory disturbance analogous to that which, in more advanced cases of diabetes, brings on localised gangrene of the hands and feet.

NOTHNAGEL ON RENAL TUBE-CASTS IN CASES OF JAUNDICE.—Professor Nothnagel (*Deutsches Archiv für Klinische Medizin*, October, 1873), found tube-casts in the urine of a young man who was suffering from simple icterus catarrhalis; with the passing away of the jaundice, the tube-casts disappeared. Since that time he has investigated a large number of cases of jaundice, and he has arrived at the conclusion that whenever the jaundice becomes intense, and more especially if the urine contain the biliary acids, renal tube-casts appear in the urine. He therefore considers that the appearance of tube-casts should be classed amongst the more constant symptoms of jaundice. In the cases where tube-casts

were not found, the jaundice was slight from the commencement, or it was passing away when the patient came under observation. The number of casts was very variable; in some cases they were numerous, while in others only two or three could be found in from four to six preparations. The number of casts seems to bear a direct relation to the intensity of the jaundice. In the great majority of cases the casts were hyaline, some of which contained a variable number of small glistening yellow granules; not rarely, unmistakable epithelial casts appeared, containing closely crowded stained kidney-epithelium. There were also found kidney-epithelium unconnected with casts, bladder-epithelium, and leucocytes. The author concludes that the bile-acids are the cause of the renal tube-casts in these cases; and he assumes that the phenomena have hitherto escaped notice, or have been considered as accidental, or at the most as an occasional result of acute yellow atrophy of the liver.

[Upon this the Reporter begs to state that in his book on *Diseases of the Kidney*, published in the year 1852, he has referred to this subject in the following terms (pp. 108-9). 'When from any cause the functions of the liver are so imperfectly performed as to allow of bile accumulating in the blood, the urine is found to be deeply tinged with some at least of the constituents of the biliary secretion; and on a microscopical examination of the urine, we find the renal secreting cells in variable numbers, some being scattered, while others are entangled in moulds of the kidney-tubes; and all of them coloured by the bile contained in them. Thus it appears that, when the blood circulating through the kidney contains an excess of bile, the renal cells in eliminating these materials become deeply tinged by it, and many of them are so far modified as to be shed by a process of desquamation.'

Again, in the Reporter's recently published *Lectures on Bright's Disease*, the subject is thus referred to (p. 31). 'When in consequence of obstruction of the gall-duct, or other disease or accident, causing an accumulation of bile in the blood, bile-products in large quantities are secreted by the kidneys, desquamated renal epithelium tube-casts, and sometimes albumen, are found in the urine. The excretion of these new products sometimes causes a mild form of desquamative nephritis. I refer to these facts to illustrate a physiological principle.' The physiological principle here referred to is, that the desquamation of the renal epithelium is a result of the excretion of some abnormal materials by the gland.—*Rep.*]

GEORGE JOHNSON, M.D.

BEARD ON SPINAL CONGESTION AND LOCOMOTOR ATAXIA.—In a paper in the *Philadelphia Medical Times* for January 24, 1874, Dr. George M. Beard makes the following assertions with regard to spinal congestion. 'The groups of sensory and motor symptoms that are caused by spinal congestion are as follows.'

1. Headache. 'The nerves that ache are those which take their origin in the cervical region of the cord, or in the lower part of the brain.'

2. Stiffness of the neck, with tenderness and pain in the cervical vertebræ.

3. Heat and pain down the spine, with or without tenderness.

4. Feeling of pressure on the chest.

5. Dyspnoea and palpitation. 'These symptoms

would very naturally arise from severe congestion of the dorsal region of the cord.'

6. Feeling of constriction around the abdomen.

7. 'Incontinence, with dribbling of the urine, constipation, or diarrhoea.'

8. Excessive sexual excitement, with erections and emissions. This 'is analogous to the startling activity and brilliancy of the brain which sometimes precede insanity, or to the ferocious and gnawing appetite that attends the early stages of dyspepsia.'

9. Sensory and motor disturbances of a mild character, in the upper and lower limbs. 'There may be mild hyperæsthesia or anæsthesia.' Neuralgic pains of a sharp, shooting, boring, stabbing character, run up and down the limbs. Twitchings of the muscles or fibrillary contractions. Jerking of the body or limbs on going to sleep.

10. Fixed paralysis of motion or sensation, or of both, in the limbs, with or without muscular contraction.

'Nearly all these symptoms, or at least very many of them, may come from precisely the opposite condition, anæmia, with exhaustion of the cord.' He who says it is an easy matter to distinguish between the symptoms due to congestion and those due to anæmia, 'is either a very great genius or a very great fool.'

The diagnosis must rest upon the following points.

1. The history of the case. 2. The symptoms coming from spinal congestion are more or less fixed and permanent, and are usually worse when the patient is in a recumbent position. 3. Spinal congestion is more likely to occur in the sanguine, bilious, and lymphatic temperaments; exhaustion in the nervous temperament. 4. The female sex is less disposed to congestion of the spine than the male sex. 5. The tenderness over the vertebræ is usually much greater when the cord is exhausted than when it is congested. 6. The result of treatment is invaluable to clinch the diagnosis. If we fancy the symptoms to be due to anæmia, and find that strychnine makes the patient worse instead of better, a mistake in diagnosis has been made, and we may turn 'right about face' and give ergot.

Dr. Beard's treatment for spinal congestion is electricity, either galvanism or faradism, and the free use of ergot and iodide of potassium.

[Many of the above assertions are startling and novel; but Dr. Beard does not lay before us the facts upon which they are founded.—*Rep.*]

G. V. POORE, M.D.

SURGERY.

MOSETIG-MOORHOF ON INTRABUCCAL RESECTION OF THE INFERIOR DENTAL NERVE AFTER PARAVICINI'S METHOD: RECOVERY.—Dr. Mosetig-Moorhof, of Vienna, says (*Wiener Medizinische Wochenschrift*, March 21, 1874), that the various methods for the division of the inferior dental nerve which have been proposed in cases of severe neuralgia are as follows. The vast superiority of the process invented by Paravicini will be at once perceived.

1. Division of the cheek through its entire thickness, at a spot corresponding with the anterior edge of the ramus of the jaw, without dividing the mucous membrane.

2. Division of the cheek at a spot corresponding with the sigmoid notch, in a direction outwards.
3. Division of the soft parts over the posterior border of the ramus of the jaw, in a direction from behind and below, inwards and upwards.
4. Removal of a portion of the angle of the jaw.
5. Trephining the ramus above the commencement of the canal after division of the soft parts.

The method adopted in the case reported by Dr. Mosetig-Moorhof was as follows. The mouth being widely opened, the mucous membrane is divided along the anterior border of the ramus of the jaw, and the finger is directed between the bone and the internal pterygoid muscle to the lingula. The separation of the inferior maxillary from the gustatory nerve is not difficult, since the former passes into the canal and the latter does not. The operation, however, is so far difficult, since the eye cannot be of any assistance, and the operator must trust to his power of touch, and has to work in a very constricted and narrow space; but the result is great relief to the patient, and no disfigurement at all as there is after the before-mentioned methods.

Dr. Mosetig-Moorhof operated on his patient on July 31, and, having found the lingula, divided the internal lateral ligament of the jaw. The nerve and artery were secured by a thread, which was passed round them by means of a small aneurism-needle (it being absolutely necessary to fix them in order to cut through the nerve centrally), and so removed a piece of it. A piece of nerve about four inches long was removed. The reaction which followed a cessation of the neuralgia, and a want of feeling of the right side of the lower jaw, was trifling. Beyond a swelling of the side of the face and pharynx, with some slight difficulty of swallowing, the patient had little to complain of.

The patient was perfectly well by the end of January, and had lost all symptoms of neuralgia.

EDWARD BELLAMY.

SAYRE ON FRACTURE OF THE CLAVICLE.—Dr. L. A. Sayre, in a clinical lecture at the Bellevue Hospital in New York (*Philadelphia Medical Times*, April 11), says that fracture of the clavicle is one of our most common fractures, yet is most difficult of treatment, as is indicated by the endless variety of apparatus suggested for its adjustment and retention. Dr. Paul Eve, of Nashville, Tennessee, has even resorted to cutting down on the fractured ends and wiring them together. In fractures we have one general law of treatment: extension and counter-extension in the proper direction until accurate adjustment, then retention. In these cases, for several years Dr. Sayre has used, with marked success, two strips of strong adhesive plaster (Maw's moleskin), without any axillary pads, three or four inches wide, one long enough to surround the arm and go completely around the body, the other to reach from the sound shoulder around the elbow of the fractured side and back, to the place of starting. The first piece is passed around the body below the axillary margin, and is pinned in the form of a loop sufficiently large to prevent strangulation, leaving a portion on the back of the arm encased by plaster. The arm is then drawn downward and backward until the clavicular portion of the pectoralis major muscle is put sufficiently on the stretch to overcome the sterno-cleido-mastoid, and thus pull the inner portion of the clavicle down to its level. The plaster is then carried smoothly

and completely around the body and pinned to itself on the back, to prevent slipping. This first strip fulfils a double purpose. First, by putting the clavicular portion of the pectoralis major on the stretch, it prevents the clavicle from riding upward; and, second, by acting as a fulcrum at the centre of the arm when the elbow is pressed downward, forward, and inward, it forces the other extremity of the humerus, and with it the shoulder, upward, outward, and backward. It is kept in this position by the second strip, applied as follows: commencing on the point of the shoulder of the sound side, drawing it smoothly diagonally across the back to the elbow of the fractured side, where a slit is made in its middle to receive the olecranon; a soft piece of muslin over the joint of the elbow is of advantage. Before applying the strip, an assistant presses the elbow well forward and inward, and retains it there while the plaster is continued over the elbow and fore-arm, pressing the latter close to the chest and securing the hand near the opposite nipple, crossing the shoulder at the place of beginning, and there securing by pins. The patient can be well shaken and no displacement occur. If any slack occur it should be taken up at once. Bandages do not stick, but slip around the body and give no firm support. The plaster should never be warmed. Sternal dislocations of this bone are also to be treated in this way, with the addition of a third piece of plaster, and a pad over the point of displacement. The strip passes diagonally across the shoulder and body, and its ends are secured to the first piece, or both.

SAYRE ON SUBPERIOSTEAL RESECTION OF THE HIP-JOINT.—In a clinical lecture, Dr. Sayre, of New York, describes the following as his plan of performing subperiosteal resection of the hip (*Philadelphia Medical Times*, April 11). Take a short, strong knife, send it home to the bone at a point midway between the anterior superior spinous process of the ilium and the top of the trochanter major; carry the knife downwards in a slight curve until you reach a point opposite the trochanter minor, not passing over the centre of the trochanter, but half-way between its centre and outer border. The incision should be six or eight inches long; boldly divide all tissues and the periosteum, and do not dissect as for hernia. Opposite the trochanter minor, divide with a probe-pointed bistoury the periosteum as far around the bone as possible, at right angles to the first incision, and at its lower limit; a knife is used to cut the rotators attached in the digital fossa; peel off all the periosteum carefully and effectually, from the diseased bone; by adducting the limb slightly, the bone is denuded of periosteum down to the trochanter, where a chain or metacarpal saw divides the shaft. Several sections are often needed to reach sound bone; this is done by pushing the ends of the femur through a slit in the periosteum. We then gouge out diseased bone from the acetabulum, wash out the wound, and fill it with balsam of Peru and oakum, thus allowing more space for new bone, the periosteum being left intact. Never leave the trochanter major; it would plug up our drain-pipe from the diseased acetabulum. Free drainage is essential to success; hence use oakum, and by no means lint or cotton. Place the patient in 'wire breeches'—a machine consisting of wire frame, which encloses the body from head to feet, fixing immovably the whole lower half of the body. The sound limb is secured to one leg of the machine,—care being used to stiffen the knee, thus

The foregoing experimental results of the analyses of the samples of milk taken direct from the udders of forty cows belonging to three large dairies, prove that the standard for genuine or normal milk which has recently been put forward for the guidance of city analysts is far too high. The assumed standard declares that normal milk must have 12.5 per cent. of total solids, of which 9.3 per cent. are solids not fat, and 3.2 per cent. must be fat. This so-called standard has been assumed in the face of an analysis

of average country milk, which is also quoted, and which average milk contains actually less than the assumed standard which ought to indicate minimum and not average quality of genuine milk. According to this so-called standard, adopted in so arbitrary a manner and blindly followed by town analysts, by far the greater number of the samples of milk taken direct from the udders of the forty cows in the dairies A. B. and C. would be held to be adulterated, either with water or with skimmed milk, or with both; and, taking the average of the whole of the samples of milk, which shows only 2.44 per cent. of fat, we find that it contains about 25 per cent. less fat than the assumed standard, so that the entire bulk of the genuine milk yielded by the forty cows, if mixed together in equal quantities, would be held to be adulterated with about 25 per cent. of skimmed milk. The results obtainable from the assumed high standard should not, therefore, be depended upon; and yet, by calculation from such data, carried out to the tenths and hundredths of a grain, we find prosecutions taking place and convictions attempted to be obtained and enforced.

The assumption of a definite high standard for milk, and the further assumption that all milk is of equal, or nearly equal, quality, is even directly contrary to all previous researches on the subject, as shown by the great diversity in the composition of milk as given in analyses published in different chemical treatises. Even the amount of fat in cows' milk on which the proportion of adulteration with skimmed milk is based, is authoritatively stated to be sometimes as low as 1.25, 1.4, 2.13, though ranging up to 3.42, 4.56, &c., showing great variations in the amount of this ingredient. Probably the best evidence on this point is given in a Government report, written by Professor John Wilson in 1866, where the Danish dairy farms are referred to, and where the variations in the amount of fat in milk are observable in the amount of milk required to yield a pound of butter at different seasons of the year. The proportions range in the same dairy farm from 19½ to 33 lbs. of milk, and in another dairy farm from 21½ to 31½ lbs. of milk, which must be employed to yield a pound of butter.

Since the analyses of the samples of milk were made by me, and I was called upon to give evidence in two cases of alleged adulteration, there has been published in the *Pharmaceutical Journal*, an excellent paper by Professor Voelcker, 'On Milk, its Supply and Adulteration,' in which he gives the results of the analyses of the milk yielded by the herd of cows at the Royal Agricultural College, Cirencester, during eleven months of a year, and shows the great variations which occur in the quality of the milk obtained from the whole herd. The total solids range from 9.3 to 13.8 per cent. and the fat from 1.79 to 4.12 per cent.; and, judging from the assumed high standard adopted by some town analysts, the whole runnings of this herd of cows would have been declared to be adulterated for two-thirds of the year.

The Adulteration Act was framed for the protection of the public, and, if properly worked out, would undoubtedly lead to the suppression of adulteration in food, drink, and medicine, and would at the same time be of national service, and a protection to the honest merchant against the dishonest and fraudulent dealer. But if anything is calculated more than another to render the Act inoperative and untrustworthy, it is the framing and setting up of a standard

of genuineness which can seldom be reached by the genuine article itself; and by blind adherence to which the majority of the samples of the genuine and unadulterated material must be declared to be mixed and adulterated.

Considering the great variations in the quality of genuine milk and the beneficial effects of the good feeding of the cows upon the milk, it is worthy the attention of dairymen whether they would not sell their milk under a guarantee of quality, say 11 per cent. of total solids, of which 9 are solids not fat and 2 are fat. In large dairies this could be ensured by mixing the whole runnings of the milking of the herd in a common tank, and thereafter filling the sale or town cans from this mixture of the whole milking. Milk could thus be sold with a guarantee which would give certainty to the purchaser that he was obtaining not only genuine milk, but genuine milk of good quality.

Since reading the foregoing paper before the meeting of the society, I have had the opportunity of testing the quality of the milk yielded by the cows in another dairy which supplies milk to Edinburgh. This dairy, which we may call dairy D, contained six cows at the time when complaints were lodged against the genuine character of the milk, and I have tested the quality of the milk given by each of these six cows in the morning, at noon, and in the afternoon. My assistants, Mr. William Ivison Macadam and Mr. Charles Edward Bourchier, went to the dairy on each occasion, inspected the milk-pails, saw all the cows milked, sampled each milk from the whole runnings taken from the udder of each cow, and brought the samples to me in a locked case. The analyses were made by me in the manner stated before, and the results obtained are given in the following table.

| No. of Cow. | Specific gravity of milk. | Cream per cent. by vol. | Total solids per cent. by weight. | Solids not fat, per cent. by weight. | Fat per cent. by weight. | Ash in solids per cent. by weight. |
|--|---------------------------|-------------------------|-----------------------------------|--------------------------------------|--------------------------|------------------------------------|
| <i>Morning Milk.</i> | | | | | | |
| 1 whole runnings | 1034.5 | 6 | 11.52 | 9.76 | 1.76 | 0.72 |
| 2 " | 1033.3 | 5 | 10.63 | 9.05 | 1.58 | 0.68 |
| 3 " | 1033.4 | 6 | 10.96 | 9.22 | 1.74 | 0.69 |
| 4 " | 1032.3 | 8 | 12.29 | 9.75 | 2.54 | 0.74 |
| 5 " | 1033.3 | 6½ | 11.04 | 9.18 | 1.86 | 0.71 |
| 6 " | 1034.1 | 6 | 10.95 | 9.21 | 1.74 | 0.73 |
| Average of morning milk | 1033.5 | 6½ | 11.23 | 9.36 | 1.87 | 0.71 |
| <i>Noon Milk.</i> | | | | | | |
| 1 whole runnings | 1033.1 | 8 | 12.94 | 10.23 | 2.71 | 0.71 |
| 2 " | 1030.9 | 9 | 12.78 | 9.66 | 3.12 | 0.70 |
| 3 " | 1032.2 | 7 | 11.42 | 9.26 | 2.16 | 0.72 |
| 4 " | 1032.3 | 8 | 11.98 | 9.37 | 2.61 | 0.73 |
| 5 " | 1030.7 | 8½ | 12.66 | 9.70 | 2.96 | 0.70 |
| 6 " | 1030.9 | 10 | 13.73 | 10.26 | 3.47 | 0.72 |
| Average of noon milk | 1031.4 | 8½ | 12.58 | 9.74 | 2.84 | 0.71 |
| <i>Afternoon Milk.</i> | | | | | | |
| 1 whole runnings | 1033.0 | 7½ | 12.52 | 10.08 | 2.44 | 0.73 |
| 2 " | 1031.1 | 8 | 12.09 | 9.33 | 2.76 | 0.71 |
| 3 " | 1030.2 | 10 | 13.11 | 9.86 | 3.25 | 0.73 |
| 4 " | 1028.3 | 8 | 11.25 | 8.62 | 2.63 | 0.74 |
| 5 " | 1031.4 | 9½ | 12.81 | 9.69 | 3.12 | 0.70 |
| 6 " | 1030.8 | 10 | 12.84 | 9.58 | 3.26 | 0.72 |
| Average of afternoon milk | 1030.8 | 9 | 12.43 | 9.52 | 2.91 | 0.72 |
| Total average of morning, noon, and afternoon milk | 1031.9 | 8 | 12.08 | 9.54 | 2.54 | 0.71 |

These results prove that, taking either a single cow or the whole herd, the morning milk did not come up to the assumed high standard of 12.50 of total solids, of which 9.30 are solids not fat, and 3.20 are fat; the noon milk only gave one sample above the standard, whilst the five remaining samples were below the standard; and the afternoon milk gave two samples equal to the standard and four samples below it. Of the whole eighteen samples only three were up to the standard and fifteen were below it, so that the milk of these fifteen cows would have been declared mixed or adulterated with water, or skimmed milk, or with both water and skimmed milk, according to the assumed high standard. Again, taking the whole morning milk, the whole noon milk, or the whole afternoon, separately or together, the entire runnings of this dairy would on the same standard be declared to be adulterated.

The differences in the quality of the milk yielded by the same cow at different periods of the day, and the variations in the character of the whole milk given by the whole herd at morning, noon, and afternoon, are markedly observable in the results obtained from dairy D. It is quite apparent that the morning milk is the poorest, whilst the noon and afternoon milks are decidedly richer. It may be stated that all of those cows were of the Ayrshire breed, that they were fed on druff, turnips, oats, straw, and peas meal; that no. 1 cow calved in August and the milk was almost out, nos. 2 and 5 calved in February, no. 3 in January, and no. 6 in September, and the milk of the latter was nearly done.

In conclusion I may mention that out of 66 samples of genuine milk taken from 46 cows, and which have been fully analysed by me, only eleven of these samples came up to the high standard of 3.2 per cent. of fat, of which one sample was of the last runnings of the milk, and three samples were deficient in the high standard of 9.3 of solids not fat; so that only seven samples of the whole runnings of milk came up to the assumed high standard on all points. Neither the average quality of the genuine milk obtained from any one of the four dairies nor the average quality of the genuine milk yielded by all the dairies taken together was equal to the arbitrary high standard assumed by city analysts.

DUBLIN ANALYST'S REPORT FOR 1873.*—During the year 1873 Dr. Cameron made 386 analyses of food and drink, of which 108 were adulterated, 16 pure, but of bad quality, and 262 pure. Of the adulterated specimens, the milk was adulterated with from 12 to 120 per cent. of water, but with no other adulterant. The bread was adulterated with alum, and in some instances it contained a large quantity of sandy matter. The flour was adulterated with alum, and six of the samples contained grit or sandy matter. The tea was composed of exhausted and decayed leaves, strengthened by the addition of some stringent gums. The coffee was adulterated with chicory and burnt sugar. The rum was wholly spurious, being new whisky, sweetened with treacle, and being 25 per cent. under proof. The butter examined contained no foreign matter, but four samples were rancid and unfit for use. The oatmeal was very mouldy, full of fungoid growths, and unfit for use.

* Twelfth Annual Report of Charles A. Cameron, Ph.D., M.D., Analyst to the City of Dublin.

Twenty-three well-waters used in Dublin were examined, and of these sixteen proved to be loaded with dangerous organic impurities, and were utterly unfit for use.

Fourteen specimens of green wall-paper on sale in the city were examined, and fourteen of them found to be coloured with arsenical green.

The following quantities of food were condemned as being unsound.

| | lbs. |
|--------------------------------|---------|
| Beef | 147,815 |
| Veal | 2,100 |
| Mutton | 6,640 |
| Pork | 19,356 |
| Bacon | 7,139 |
| Fish | 34,220 |
| Butter | 72 |
| Fruit and vegetables | 450 |
| Bread | 6,000 |
| Flour | 560 |
| Tea | 200 |
| Total | 224,552 |

The fines and costs imposed on 43 persons convicted for selling adulterated food amounted to 252*l.* 11*s.*

Of the 21 persons convicted for selling or being possessed of diseased or unsound meat, 11 were fined 49*l.* 17*s.* The others, 10, were imprisoned—3 for 3 months each, 3 for 2 months each, 2 for 6 weeks, and 2 for 14 days each.

During the last four years 1,438 sanitary analyses have been performed, 1,432,521 lbs. of unsound food condemned, 139 persons fined for selling adulterated food, 72 persons fined for selling or having in their possession diseased meat, and for the latter offence 21 persons were imprisoned for periods varying from 14 days to 3 months. The fines imposed amounted to nearly 1,000*l.* The names, offences, &c., of several adulterators were advertised at their own expense in the newspapers.

THE DRAINAGE OF COWFOLD.—The medical officer of health for East Sussex, Dr. E. F. Fussell, has just presented to the rural sanitary authority a concise and able report on the drainage of Cowfold and Ardingly, and on some other sanitary matters in connection therewith.

The sewerage seems to be very defective, the main sewer commencing as a pipe, being constructed as a drain partly built of brick and partly of stone, and finishing up as an open ditch, which passes 'within a few feet of the back premises of a large private school, taking the slops but not the sewage of this establishment,' and ends by joining a stream, the water of which the cattle drink. The medical officer rightly denounces this state of things as injurious to health and proposes three alternatives, viz. :—

1. To construct a proper well ventilated sewer, establish a system of precipitation near the present outfall, filter the effluent water and discharge it into the stream.

2. To divert the sewage into a cesspool in the field adjoining the outlet and utilise it by pumping it over the land for surface irrigation.

3. To leave the present sewer for the conveyance of surface-water only, allowing no overflow of privies and no slops to be discharged into it, and requiring the owners of houses to construct earth or ash closets.

The first plan he condemns as costly, complex, and a probable failure, and certainly if the subsequent filtration were not very thoroughly performed, or if

the effluent water from the precipitation process were not used for irrigation, it is more than likely that such would be the case.

The second suggestion has the difficulty that the consent of the landowner and tenant would be required, that the rain-water would probably have to be separated from the sewage proper, so that it might not be too dilute, and that subsequent owners or tenants of the land might object; these are serious difficulties, which might, however, be met by the purchase by the sanitary authority of a suitable piece of land, and we consider that sewage irrigation schemes should not be undertaken unless this is done; part of the sewage may be let out to farmers around, and this is done at some places; but the sanitary authority should have within their own control the means of satisfactorily purifying the sewage of the district. The difficulty suggested that if the rain-water were diverted the sewer would require flushing occasionally by a water cart, would be met by making it possible to divert the surface-waters into the sewer when necessary.

The third plan is the one to which the medical officer leans, and there can be no doubt that the substitution of efficiently constructed ash- or earth-closets, with frequent removal of the contents, for privies, would be a great improvement, especially as waterclosets do not appear to be in use at present at any rate; we have our doubts, however, as to whether it would be practicable to keep the dirty water, slops, &c., out of the drains, and expect that the question of purifying the sewage will come up again sooner or later; still the plan proposed would be, we repeat, a great improvement.

Dr. Fussell urges 'that the sanitary authority should compel all owners of cottages to lay on the water from the main,' and advises that in those places which the main does not reach the drinking-water should be boiled before being used.

DERMATOLOGY.

SIMON ON IMPETIGO CONTAGIOSA.—We extract the following from the *Berliner Klinische Wochenschrift* for February 23. Dr O. Simon brought forward two cases of the above disease as the first observed in Germany [he must have excluded the Austrian Empire pathologically as well as politically from *Deutschland*], which were discussed at the Medical Society of Berlin, last December. The first patient was a painter; and soon afterwards his wife was also attacked. The second case occurred in the child of a weaver, who caught the affection at school, and transmitted it first to his father, and then to his mother. The third instance [apparently not exhibited] was that of a railway navy, who caught it from his child and gave it to his wife.

After referring to the name 'Impetigo Tartini' given to this disease by Mr. Dunn, to Dr. Tilbury Fox's careful description of it in 1864, and to Kaposi's discovery of a fungus in 1871, the author stated that microscopical examination in his cases had only shown the presence of *Acarus* [*Demodex*] *folliculorum*, ordinary micrococci, and, in a single instance, spores and mycelium like those of *Achorion Schaeleinii*. He pointed out the difference between impetigo contagiosa and ordinary pustular eczema, in the isolated localisation of the eruption, the absence of infiltration of

the skin, of redness and of subsequent desquamation, beside the character of contagion.

Dr. Lewin quoted a case from Taylor published in the *Boston Medical and Surgical Journal* for 1872, where the disease affected three children and their mother. He could not accept it as a *morbus sui generis*, but regarded all pustules as more or less contagious, and quoted instances in which ordinary vesicular as well as impetiginous eczema was contagious. Failure to inoculate with ordinary pustules proved nothing, for the same often occurs with such undoubtedly contagious diseases as Pemphigus [?] and Molluscum contagiosum.* He thought the case in which achorion was found must be regarded as one of ordinary favus (*Tinea favosa*). In reply, Dr. Simon argued that, though any pustule might be contagious, it would only produce another like itself, not a complete disease with its characteristic symptoms and course. Moreover, he thought that the apparent contagion of cases of ordinary eczema was really to be explained as the result of a common cause, e.g. bad soap in a household, which he had seen produce an apparent epidemic of eczema. He could not admit any relation of impetigo contagiosa to scrofula, nor that it in the least resembles what used to be called impetigo, but is now generally recognised as a mere variety of eczema.

NEUMANN ON CUTANEOUS ERUPTIONS FOLLOWING THE USE OF BROMIDE OF POTASSIUM.—Neumann (in a paper read before the k.k. Gesellschaft der Aerzte of Vienna, February, 1873) describes two cases of cutaneous eruption following the internal use of bromide of potassium. A child, a year and a-half old, had been taking a grain of the salt morning and evening for convulsions, and the dose was gradual raised from one to five grains twice a day. When seen, it had suffered four weeks from an eruption of suppurating sebaceous tumours, of various sizes, on the forehead, cheeks and limbs. Two (on the face and leg) were as large as half-crowns. There were no comedones, and the age of the patient alone [beside the distribution of the affection] put the question of acne aside; while the author regards the fact of suppuration having occurred in almost all the tumours as negating the diagnosis of molluscum sebaceum [M. contagiosum of English authors]. The appearance of fresh nodules only ceased when the administration of the drug was stopped.

The second case was that of a man, aged forty-two, who during twelve months had taken from fifteen to thirty grains of bromide of potassium every day, for headache. After about nine months furunculoid swellings appeared on the forehead, the neck, and the parts of the face which were covered with hair. (There is no further evidence given of the etiology of the eruption.)

KOBNER ON ZOSTER.—In a paper read before the Silesian Gesellschaft für vaterländische Cultur, May 30, 1873 (quoted in Pick & Auspitz's Journal) Köbner describes a typical case of zona following the distribution of the small sciatic nerve and its pudendal branch, over the back of the thigh, half the perineum,

* In Virchow's *Archiv* for 1873 is a paper by Dr. Bollinger on this disease (which he most inconveniently calls Epithelioma contagiosum), where evidence is offered of its identity with a contagious disease known among poultry as hen-pox.

scrotum, and penis. The eruption was ascribed by the patient to his having sat down while hot upon damp grass.

WIGGLESWORTH ON PRURIGO FEROX.—Dr. Wigglesworth (*American Journal of Syphilis and Dermatology*, vol. iv.), describes a case of prurigo ferox universalis (Hebra's prurigo) in a boy aged fourteen. The papules were most numerous on the flexor side of the wrist, and on the palms and soles, but were more or less present everywhere, least so in the face. There was great anæmia. The treatment was, internally, cod-liver oil and steel, with chloral to procure sleep; externally, Hebra's modification of Wilkinson's ointment. [℞ Sulphuris sublimati, Olei fagi aa ʒvj, Cretæ preparatæ, ʒiv, Saponis viridis, Axungiæ aa libram j.—*Rep.*]

Under this treatment the symptoms quickly subsided, and the skin was restored to its healthy condition.

HOFMANN ON A CASE OF CHROMIDROSIS.—Hofmann (*Wiener Medizin. Wochenschrift*, 1873, no. 13), puts on record a case of chromidrosis of the scrotum and adjacent part of the thigh in a man seventy-two years old. The colour was bluish-black, and indigo was detected; after reducing the pigment to indigo-white, it was seen to regain its colour by exposure to the air.

OLLIVIER ON PARTIAL HYPERIDROSIS OF THE FACE.—Dr. Ollivier (*Gazette Médicale de Paris*, 1873, no. 24), relates a remarkable case of local hyperidrosis of the part of the face supplied by the second division of the fifth nerve, in a man whose maternal grandfather, a daughter of the latter, with one of her children, were subject to the same curious affection. The mother of the patient was free.

P. H. PYE-SMITH, M.D.

LEISRINK ON LIGATURE OF THE FEMORAL ARTERY IN ELEPHANTIASIS OF THE LEG.—Dr. Leisrink relates (*Deutsche Zeitschrift für Chirurgie*, December, 1873) the case of a woman who consulted him on account of elephantiasis of the right leg, from which she had suffered for twenty-five years. It had followed repeated attacks of erysipelas. From the ankle-joint to more than half way up the leg, the limb was covered with a crust like the bark of an old tree. From large and deep furrows in it was discharged an abundant quantity of a limpid fluid. She was unable to use the limb, and her general health was much impaired.

Dr. Leisrink tied the femoral artery below Poupert's ligament. The result of the operation was that the discharge ceased, the patient became able to use the limb, and her general condition improved. The following are the measurements round the limb, in inches, before and ten months after the operation.

| | Before Operation. | After Operation. |
|--------------------------------|----------------------|---------------------|
| Below the knee . . . | 17'3 . | 13'7 |
| At the middle of the leg . . . | 22'8 . | 13'4 |
| Above the ankle . . . | 16'5 . | 5'1 |

A. HENRY, M.D.

RECENT PAPERS.

Communication of Herpes to Man from Animals suffering from Herpes and Scabies. By Dr. P. Michelson. (*Berliner Klinische Wochenschrift*, nos. 11 and 12, 1874.)

NEW INVENTIONS.

J. & F. ALLEN'S IMPROVED ENEMA AND DOUCHE WITH BIDET.

This apparatus is made of strong tin, and is mounted on a stand with mahogany top, and enamelled white inside, the outside enamelled in imitation of wood, marble, or china, as desired. The back part forms the bidet; the front forms a compartment for holding warm or cold lavements or injections, and in which the pump is fixed. There is also a silvered jar for medicated lotions or enemata. Both pump and jar can be instantly removed for cleansing, by lifting out

the small band round the pump, by which it is held firmly in its place. The tubes from the pump are jointed in such a manner that they can be raised or lowered at pleasure; and each of the injection-tubes can be reversed from the end to the middle joint, or vice versa, so as to serve every form of application, for male or female use. It has an elegant appearance, when placed in any bed or bath-room, is most simple in construction, requires no attendant by the person using it, is the only apparatus that can be used as a douche or enema with comfort, and we believe it to be unique. It is also made to pack up for travelling.

PHOSPHORISED COD-LIVER OIL.

The therapeutic uses of phosphorus have lately attracted greatly increased attention in the profession. There is a general concurrence of opinion as to its great value in many forms of nervous exhaustion, and there are many examples of its almost magical effect in some cases of obstinate neuralgia. Messrs. Young and Postans, 35 Baker Street, have forwarded to us a preparation of phosphorised cod-liver oil, one of the most useful combinations in which phosphorus could be ordered. Its flavour is well disguised, so that the preparation is as nearly tasteless as possible. It is a very desirable as well, we think, as a popular medicine.

BROMO-CITRATE OF LITHIA WATER.

This mineral water is newly introduced by Mr. Robert Hogg, 9 Albion Place, Hyde Park. It is a

very elegant and useful combination of remedies for which, in cases of chronic rheumatism, physicians have a well-founded predilection. It contains bromine, with the citrates of lithia, potash, and ammonia in the doses usually prescribed, and they may of course be varied to order. This is a very pleasant and useful mode of prescribing, and we think this water is likely to be much appreciated.

REVIEWS.

Asthenic Insanity. By STRETHILL H. WRIGHT, M.D. Edinburgh: Oliver & Boyd.

Dr. Wright has collected various papers published by him in the *Edinburgh Medical Journal*, on the varieties of 'Asthenic Insanity,' which is, he says, a constitutional malady. It is a disordered state in which the vigour of the whole organism is much reduced—reduced to an asthenic condition; but wherein disorder of the mental operations is manifested by the patient as the most prominent symptom of the state of general asthenia to which the brain, in common with the whole organism, has been reduced. On the contrary, 'sthenic insanity' expresses the nature of those cases where mental disorder depends, not upon diminution of the constitutional vigour, but upon the undue excitement of the mental functions by various influences originating from constitutional conditions, temporary or permanent. The term 'asthenic' does not define the nature of the mental manifestations, but denotes a general depravity of the constitution, in consequence of which brain-disorder arises. The brain may be primarily at fault, or its action may be directly influenced by the disorder of some organ more remote. The subject is treated under three heads.

1. When mental disorder depends on constitutional morbid modifications, which do not intrinsically progress towards a fatal result, and are not irremediable.

2. When mental disorder depends upon constitutional modifications of an irremediable nature.

3. When the complexion of the insanity, originally of another type, assumes an asthenic caste in consequence of the supervention of some bodily disorder of a special kind.

Under the first head cases of insanity are ranged, in which mental disorder results from constitutional modifications dependent upon the severe or protracted depressing influence of physical disorder—exhaustion of the brain and nervous system by undue exercise or trial of their special energies. These varieties are illustrated by cases of patients admitted into the Royal Edinburgh Asylum.

Under the second head may be classed the great majority of cases of recurrent insanity, especially those where insanity recurs at short intervals; where it is excited by trivial causes, and where the asthenic condition of the constitution generally, but especially if the nervous system, is congenital; where the predisposition is not hereditary, but acquired by prolonged or severe periods of trial, the constitutional vigour being materially and permanently depressed; and, finally, those cases in which insanity is produced as a symptom of the general constitutional incompetence caused by chronic disease of a specific kind.

The cases belonging to this variety are incurable. The state of the patients is susceptible of ameliora-

tion, but never of lasting recovery: they are never fitted for holding office involving personal responsibility during a prolonged period.

A case is given illustrating the third variety. The patient, when admitted, was in a state of sthenic insanity, and remained in this state so long as her bodily health continued robust; but when her constitutional vigour failed—when symptoms of an irremediable organic disease (phthisis pulmonalis) of an asthenic kind manifested themselves—then also a change was noted in the nature of her mental symptoms.

In forming an opinion as to the chances of recovery in a case where there is no specific organic disease, the history is of great importance. If the general health previously to the attack have been good, if there be no history of hereditary predisposition, if there be a clear account of causes, which from their gravity may well be accredited with the production of the asthenic state of constitution which produces mental disorder, then strong hopes of a recovery may be entertained.

If, on the other hand, the patient have inherited an insane predisposition, if the asthenic constitutional state have resulted from depressing circumstances which have been long in operation, and from the effects of which the constitution shows no disposition to rally, or if the general asthenia have resulted from incurable organic disease, the prognosis is of the most unfavourable character.

In subsequent papers, Dr. Wright gives cases illustrating these three classes. The first contains two cases of the second variety; in another, he considers the insanity due to constitutional syphilis; and one is devoted to the history of a patient suffering from what he terms ovario-mania, the uterus and ovaries being completely solidified by cancerous deposit. G. FIELDING BLANDFORD, M.D.

Schwalbach. By THEODOR FRITZE, M.D. With steel engravings. (Darmstadt, 1873.)

This is a clear, well put together account of Schwalbach, meant for popular use, and not praising the waters extravagantly. The book has very pretty little steel engravings, which will help to make it popular. It is a pity that its English is not free from Germanisms. J. MACPHERSON, M.D.

MISCELLANY.

MONUMENT TO LIEBIG.—The subscriptions collected for a monument to the late Baron Liebig amount to about 6,000 thalers.

MADAME LENOIR JOUSSEREAU, who died at the beginning of March, left her entire fortune to the Paris hospitals. It amounted to over ten million francs. She desired that it should be used for the creation of a special charity to be called Lenoir Jousseureau. She left only 500,000 francs to her distant relatives and attendants.

INTERNATIONAL MEDICAL CONGRESS.—The organisation of an International Medical Congress at Brussels in 1875, is being carried out with great activity. The president is to be Dr. Vlemmckx, president of the Academy of Medicine, who has already presided over other scientific congresses with tact and authority. The Belgian Government has promised its co-operation, but it belongs specially to the members of the medical profession to set their shoulders to the wheel, in order to make the scheme work.

A NEW FUEL.—A new combustible material, to which the name of white coal has been given, has been discovered in the Australian continent. It is formed of vegetable fibres matted together, between which a fine sand is found. It is easily inflammable, and gives a brilliant flame. This white coal, discovered in the Antipodes, has not as yet been dug up to any extent, and will doubtless be found useful as a fuel.

POOR-LAW RELIEF IN PARIS.—The Poor-law Board of Paris has been enabled to increase the annual budget to the amount of 28,150,000 francs, of which 11,500,000 francs are furnished from the municipal funds to supply the deficit in the budget. 20,161 beds have been kept up in the hospitals and refuges, of which 9,311 are for the aged and infirm, 8,277 for the sick, and 2,081 for the insane poor. 111,090 persons have been admitted into the various hospitals and refuges, and 192,000 have been attended to in their own homes, amongst whom were 10,000 lying-in women.

THE KAK-KE.—Dr. Hoffman, in a late number of the *Japan Mail*, gives an interesting description of a species of endemic disease, known as *kak-ke*, peculiar to the islands of Japan. The malady is said to possess considerable similarity to the Indian disease called *beri-beri*, and by the Dutch, and subsequently by other foreigners, was erroneously supposed to be identical with it. It makes its appearance regularly at the beginning of spring, first attacking only such persons as have suffered from it in preceding years, and on the approach of warm weather assails, also, those whom it had hitherto spared. The characteristic symptoms of the disease appear to be pain and stiffness in the lower extremities, accompanied by a diminution of sensibility and cutaneous oedema, beginning with the ankle joints and rapidly extending to the knees. In addition to these symptoms, a simultaneous occurrence of violent palpitation of the heart, to which is occasionally superadded endocarditis. The patient shows a distaste for all pursuits, and more especially those which demand exercise of intellect, while a general sense of drowsy weakness is observable. With the approach of cooler weather, the symptoms tend to disappear, even without treatment, and a slight weakness, often accompanied by anæmia, is all that now remains of the complaint; and this symptom disappears, also, in the course of the winter. In the more severe cases, however, the cure is deferred and is often incomplete, insensibility and palsy of different degrees remaining, occasionally even to the extent of complete paralysis of the upper and lower extremities, with atrophy of the part affected. In other cases, anæmia and general debility, with trembling of the limbs, remain to mark the passage of the disease.

MR. E. BELLAMY has been appointed Lecturer on Anatomy at Charing Cross Hospital.

CHARITABLE PHARMACIES.—The *Voix* of St. Petersburg states that a plan has been laid before the proper authorities for the establishment of a philanthropic pharmacy, which shall be obliged to furnish 30,000 doses of medicine annually, at a fixed price for each of twenty-five copecks (about ninepence halfpenny.) The prescriptions entitling the holders to these medicines are to be at the disposal of the medical men of the city, to be distributed to their most destitute patients. There are many hospitals in St. Petersburg where the indigent sick can obtain medical advice and assistance at a very trifling cost; but up to the present time there has been no low-priced pharmacy, whilst the present high price of drugs renders the establishment of such a charity most desirable.

NOTICE.

THE LONDON MEDICAL RECORD is published every Wednesday morning, and may be ordered direct from the Publishers, Annual Subscription, 17s. 4d.; free by post, 19s. 6d.

Reading Covers to hold 12 numbers of THE LONDON MEDICAL RECORD have been prepared, and may be had direct from the Publishers or through any Bookseller, price 2s. 6d. each.

Foreign Books for review in this Journal may be sent addressed to the EDITOR, care of Messrs. DULAU & CO., London; and through their Agents:—Paris: Mr. G. BOS-SANGE, Rue Quatre-Septembre—Leipzig: Mr. K. F. KOEHLER—Florence: Mr. E. LOESCHER—Brussels: Mr. C. MUQUARDT.

The First Volume, containing upwards of Two Thousand Articles abstracted and compiled by a staff of Fifty Hospital Surgeons and Physicians, is now ready, price 19s. 6d. Cloth Cases for binding the Numbers for the year 1873 are also ready, price 1s. 6d. each.

Home and Foreign Agents for THE LONDON MEDICAL RECORD:—Edinburgh: MACLACHLAN & STEWART—Amsterdam: W. H. KIRBERGER—Bombay: THACKER, VINING & Co.—Calcutta: THACKER, SPINK & Co.—Melbourne: GEORGE ROBERTSON—Montreal: W. DAWSON & Co.—New York: G. PUTNAM'S SONS—Paris: JOHN ARTHUR & Co., 10 Rue Castiglione.

Advertisements should be sent to the Office, 15 Waterloo Place, S.W., before Twelve o'clock on Tuesday morning.

The London Medical Record.

WEDNESDAY, MAY 13, 1874.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BARTHOLOW'S EXPERIMENTS ON THE HUMAN BRAIN.

With a boldness which we suspect few experimenters in this country will dare to imitate, Dr. Bartholow, of Ohio, has applied the electric stimulation to the surface of the brain, in a case under his care, where the brain was exposed by an epithelioma of the scalp (*American Journal of the Medical Sciences* for April, 1874). After referring to recent researches on the functions of the brain in lower animals by the reporter and others, Dr. Bartholow proceeds to relate the results of his experiments. The case was one of an Irish domestic servant, aged thirty, who had a considerable portion of the posterior lobes of the brain exposed by disease, without any interruption of its functions. The ulceration occupied the posterior and superior border of both parietal bones. The skull was eroded over a space two inches in diameter, where the pulsations of the brain were plainly seen. Believing that fine needles could be introduced into the brain-substance without material injury to the cerebral matter, Dr. Bartholow first proceeded to test the sensibility of the dura mater to the faradic current. When the irritable granulations of the surface of the ulcer were touched, pain was experienced; but when the needle points were engaged in the dura mater, the patient (Mary) 'declared in answer to repeated questions that she felt no pain.' [This would not agree with the results of irritation of the dura mater, observed by Hitzig and myself, and it is doubtful whether accurate conclusions can be drawn from such an abnormal state of the dura mater as was here presented.—*Rep.*] 'No pain whatever was experienced in the brain-substance proper. Mechanical irritation of the cerebral matter produced no results on motility or sensibility of the extremities.' Two needles were then introduced into the left side of the brain. When the circuit was closed, muscular contractions occurred in the right arm and leg. The arm was thrown out, the fingers extended, and the leg was projected forwards. The muscles of the neck were thrown into action, and the head was strongly deflected to the right. Similar phenomena occurred on the left side, when the right side of the brain was stimulated. Another experiment on the left side caused the same effects as before, along with contraction of the orbicularis oculi and dilatation of the pupils. 'Mary complained of a very strong and unpleasant feeling of tingling in both right extremities, especially in the right arm, which she seized with the opposite hand and rubbed vigorously. Notwithstanding the very evident pain from which she suffered, she smiled as if much

amused.' Another experiment was made on the right hemisphere, and the current was intensified. 'When communication was made with the needles, her countenance exhibited great distress, and she began to cry. Very soon the left hand was extended, as if in the act of taking hold of some object in front of her; the arm presently was agitated with clonic spasms; her eyes became fixed, with pupils widely dilated; the lips were blue, and she frothed at the mouth; her breathing became stertorous; she lost consciousness, and was violently convulsed on the left side. The convulsion lasted five minutes, and was succeeded by coma. She returned to consciousness in twenty minutes from the beginning of the attack, and complained of some weakness and vertigo.' Another experiment on both sides with currents not so strong as to cause epileptic convulsions, gave results precisely the same as those indicated in previous observations.

Two days subsequently, Mary was brought down again for experimentation with the galvanic current, but the proposed experiment was abandoned, on account of the occurrence of a choreic or epileptiform fit.

The next day 'Mary was decidedly worse; she remained in bed, was stupid and incoherent. In the evening she had a [convulsive seizure, lasting about five minutes, confined to the right side. After this attack she lapsed into profound unconsciousness, and was found to be completely paralysed on the right side.' There was paralysis of motion and sensation, along with convergent strabismus and fixed dilated pupils. Without stating when death occurred, Dr. Bartholow gives the account of the *post mortem* examination of the brain. 'A thick layer of greenish-yellow pus extended over the whole of the left hemisphere, and an intense degree of vascularity existed over the whole brain.' No special appearances were observed about the points at which the needles were inserted, and the vascularity and the exudation on the left side were not apparently increased at these places.' Death was attributed to the occurrence of a thrombus in the longitudinal sinus, which was found occupying a point corresponding to the centre of the ulcer. This, along with the arachnoid inflammation, was traced to the extension of the epitheliomatous ulceration from its point of greatest depth.

The point at which the needles were inserted was found in both hemispheres, after hardening in chromic acid, to be the postero-parietal lobule (Turner) or upper parietal lobule (Ecker), into which the needles had been inserted to the depth of one inch, at a distance of about an inch from the longitudinal fissure on the left side, and somewhat deeper and more distant from the longitudinal fissure in the right hemisphere. Dr. Bartholow makes no comments on the facts of his experiments, [Whatever opinion may be entertained as to their propriety, they furnish facts of great interest in relation to the physiology of the brain. The point at which the needles were inserted (the postero-parietal lobule) corresponds homologically with that region of the brain in monkeys which the reporter has shown to be a centre for the leg. In close relation to this in the ascending parietal convolution, and in the upper part of the ascending frontal in advance of the fissure of Rolando, are centres for movements of the arm and hand. The method followed by Dr. Bartholow, of pushing the needles into the brain-substance, favours diffusion of the current, so that the

conjoint movements of the arm and hand may be looked upon as the simultaneous excitation of different individual centres. The results, however, are otherwise quite in accordance with what one would have reason to expect from irritation in this region. They distinctly bear out the anatomical and physiological homology of the brain of man with that of the monkey and lower animals. Owing to the depth of penetration of the needles, there is reason to believe that the stimulation reached the cerebral centres of the tactile nerves, which the reporter has given grounds for supposing to be near this region. This would account for the tingling and painful sensations experienced in the extremities of the opposite side. Of further interest is the occurrence of epileptic convulsions from general diffusion of the irritation when the currents were intensified. This is entirely in accordance with the reporter's observations, and the phenomena of the seizure are a complete parallel to the results in the lower animals which he has elsewhere recorded. The subsequent spontaneous occurrence of epileptic convulsions and ultimate paralysis are clearly accounted for by the inflammatory changes, at first causing irritation and then proceeding to annihilation of the function of the cortical centres, without affection of the lower ganglia. Precisely the same effects are observable in the lower animals.—*Rep.]*

D. FERRIER, M.D.

SANDER ON THE MEDICO-LEGAL ASPECTS OF EPILEPSY.
